TRANSMISSION LOSS PREDICTIONS FOR TROPOSPHERIC COMMUNICATION CIRCUITS

VOLUME 1

P. L. Rice, A. G. Longley, K. A. Norton, and A. P. Barsis
Institute for Telecommunication Sciences and Aeronomy
Environmental Science Services Administration
Boulder, Colorado

NBS Technical Notes are designed to supplement the Bureau's regular publications program. They provide a means for making available scientific data that are of transient or limited interest. Technical Notes may be listed or referred to in the open literature.

*Formerly the Central Radio Propagation Laboratory of the National Bureau of Standards. ESSA will use the NBS publication series until establishment of their ESSA counterparts.
FOREWORD

A short history of the development of the prediction methods in this Technical Note will permit the reader to compare them with earlier procedures. Some of these methods were first reported by Norton, Rice and Vogler [1955]. Further development of forward scatter predictions and a better understanding of the refractive index structure of the atmosphere led to changes reported in an early unpublished NBS report and in NBS Technical Note 15 [Rice, Longley and Norton, 1959]. The methods of Technical Note 15 served as a basis for part of another unpublished NBS report which was incorporated in Air Force Technical Order T.O. 31Z-10-1 in 1961. A preliminary draft of the current technical note was submitted as a U.S. Study Group V contribution to the CCIR in 1962.

Technical Note 101 uses the metric system throughout. For most computations both a graphical method and formulas suitable for a digital computer are presented. These include simple and comprehensive formulas for computing diffraction over smooth earth and over irregular terrain, as well as methods for estimating diffraction over an isolated rounded obstacle. New empirical graphs are included for estimating long-term variability for several climatic regions, based on data that have been made available.

For paths in a continental temperate climate, these predictions are practically the same as those published in 1961. The reader will find that a number of graphs have been simplified and that many of the calculations are more readily adaptable to computer programming. The new material on time availability and service probability in several climatic regions should prove valuable for areas other than the U.S.A.

Changes in this revision concern mainly sections 2 and 10 of volume 1, annexes I, II and V of volume 2, and certain changes in notation and symbols. The latter changes make the notation more consistent with statistical practice.

Section 10, Long-Term Power Fading contains additional material on the effects of atmospheric stratification.

For convenience in using volume 2, those symbols which are found only in an annex are listed and explained at the end of the appropriate annex. Section 12 of volume 1 lists and explains only those symbols used in volume 1.

Note: This Technical Note consists of two volumes as indicated in the Table of Contents.
# TABLE OF CONTENTS

**Volume 1**

1. **INTRODUCTION** .................................................. 1-1

2. **THE CONCEPTS OF SYSTEM LOSS, TRANSMISSION LOSS, PATH ANTENNA GAIN, AND PATH ANTENNA POWER GAIN** .................................................. 2-1
   2.1 System Loss and Transmission Loss ................................... 2-1
   2.2 Antenna Directive Gain and Power Gain ................................... 2-3

TRANSMISSION LOSS PREDICTIONS FOR
TROPOSPHERIC COMMUNICATION CIRCUITS

P. L. Rice, A. G. Longley, K. A. Norton, and A. P. Barsis

1. INTRODUCTION

This report presents comprehensive methods of calculation which have been found useful either for explaining or for predicting cumulative distributions of transmission loss for a wide range of radio frequencies over almost any type of terrain and in several climatic regions. Such quantitative estimates of propagation characteristics help to determine how well proposed radio systems will meet requirements for satisfactory service, free from harmful interference. Thus they should provide an important step toward more efficient use of the radio frequency spectrum.

The need for comprehensive and accurate calculation methods is clearly demonstrated when measured transmission loss data for a large number of radio paths are shown as a function of path length. In figures I.1 to I.4 of annex I, long-term median values of attenuation relative to free space for more than 750 radio paths are plotted versus distance. The extremely wide scatter of these data is due mainly to path-to-path differences in terrain profiles and effective antenna heights. Values recorded for a long period of time over a single path show comparable ranges, sometimes exceeding 100 decibels. Such tremendous path-to-path and time variations must be carefully considered, particularly in cases of possible interference between co-channel or adjacent-channel systems. Included in annex I is a method for obtaining preliminary reference values of transmission loss for a wide range of prediction parameters.

The detailed point-to-point methods described here depend on propagation path geometry, atmospheric refractivity near the surface of the earth, and specified characteristics of antenna directivity. They have been tested against measurements in the radio frequency range 40 to 10,000 MHz (megahertz = megacycles per second). Estimates of attenuation due to absorption and scattering of radio energy by various constituents of the atmosphere are included in order to extend the application of these methods to frequencies up to 100 GHz.

Calculations of long-term median reference values of transmission loss are based on current radio propagation theory. A large sample of radio data was used to develop the empirical predictions of regional, seasonal, and diurnal changes in long-term medians. Estimates of long-term fading relative to observed medians are given for several climatic regions and periods of time, including some regions where few observations are available.

Calculations of transmission loss for paths within the radio horizon are based on geometric-optics ray theory. For paths with a common horizon, Fresnel-Kirchoff knife-edge diffraction theory is applied and extended to predict diffraction attenuation over isolated rounded obstacles. For double horizon paths that extend only slightly beyond the horizon, a modification of the Van der Pol-Bremmer method for computing field intensity in the far diffraction region is
used. For longer paths, extending well beyond radio horizon, predictions are based on forward scatter theory. Radio data were used to estimate the efficiency of scattering at various heights in the atmosphere. Where some doubt exists as to which propagation mechanism predominates, transmission loss is calculated by two methods and the results are combined.

Examples showing how to compute transmission loss for a line-of-sight path, an isolated rounded obstacle, and a long transhorizon path are given following sections 5, 7 and 9 respectively. Section 12 provides a list of symbols and abbreviations used in the text. Special symbols used only in an annex are defined at the end of the appropriate annex.

Annex I includes a set of "standard" curves of basic transmission loss and curves showing attenuation below free space for earth space communications, prepared using the methods described in the report. Such curves, and the medians of data shown on figures I.1 to I.4, may serve for general qualitative analysis, but clearly do not take account of particular terrain profiles or climatic effects that may be encountered over a given path.

Annex II supplements the discussion of transmission loss and directive antenna gains given in section 2. This annex contains a discussion of antenna beam orientation, polarization, and multipath coupling loss.

Annex III contains information required for unusual paths, including exact formulas for computing line-of-sight transmission loss with ground reflections, as well as modifications of the formulas for antenna beams which are elevated, or directed out of the great circle plane. Analytic expressions suitable for use on a digital computer are also included.

Annex IV reviews tropospheric propagation theory with particular attention to the mechanisms of forward scatter from atmospheric turbulence, from layers, or from small randomly oriented surfaces. References to some of the work in this field are included.

Annex V presents a discussion of "phase interference fading" as contrasted to "long-term power fading", provides a method for computing the probability of obtaining adequate service in the presence of noise and/or interfering signals, and includes a brief summary of ways to achieve optimum use of the radio frequency spectrum.

2. THE CONCEPTS OF SYSTEM LOSS, TRANSMISSION LOSS, PATH ANTENNA GAIN,
AND PATH ANTENNA POWER GAIN

Definitions have been given in CCIR Recommendation 341 for system loss, \( L_s \), transmission loss, \( L_p \), propagation loss, \( L_p \), basic transmission loss, \( L_b \), path antenna gain, \( G_p \), and path antenna power gain \( G_{pp} \). This section restates some of the definitions, introduces a definition of "path loss" \( L_0 \), illustrates the use of these terms and concepts, and describes methods of measurement [Norton, 1953, 1959, Wait 1959]. The notation used here differs slightly from that used in Recommendation 341 and in Report 112 [CCIR 1963a, b]. For the frequency range considered in this report system loss, transmission loss, and propagation loss can be considered equal with negligible error in almost all cases, because antenna gains and antenna circuit resistances are essentially those encountered in free space.

2.1 System Loss and Transmission Loss

The system loss of a radio circuit consisting of a transmitting antenna, receiving antenna, and the intervening propagation medium is defined as the dimensionless ratio, \( w'_t / w'_a \), where \( w'_t \) is the radio frequency power input to the terminals of the transmitting antenna and \( w'_a \) is the resultant radio frequency signal power available at the terminals of the receiving antenna. The system loss is usually expressed in decibels:

\[
L_s = 10 \log \left( \frac{w'_t}{w'_a} \right) = W_t - W_a \text{ db} \quad (2.1)
\]

Throughout this report logarithms are to the base 10 unless otherwise stated.

The inclusion of ground and dielectric losses and antenna circuit losses in \( L_s \) provides a quantity which can be directly and accurately measured. In propagation studies, however, it is convenient to deal with related quantities such as transmission loss and basic transmission loss which can be derived only from theoretical estimates of radiated power and available power for various hypothetical situations.

In this report, capital letters are often used to denote the ratios, expressed in db, dbu, or dbw, of the corresponding quantities designated with lower-case type. For instance, in (2.1), \( W_t = 10 \log w'_t \) in dbw corresponds to \( w'_t \) in watts.

Transmission loss is defined as the dimensionless ratio \( w'_t / w'_a \), where \( w'_t \) is the total power radiated from the transmitting antenna in a given band of radio frequencies, and \( w'_a \) is the resultant radio frequency signal power which would be available from an equivalent loss-free antenna. The transmission loss is usually expressed in decibels:

\[
L = 10 \log \left( \frac{w}{w'_a} \right) = W_t - W_a = L_s - L_{et} - L_{er} \text{ db} \quad (2.2)
\]

\[
L_{et} = 10 \log \epsilon_t', \quad L_{er} = 10 \log \epsilon_r \quad (2.3)
\]
where $1/l_{et}$ and $1/l_{er}$ as defined in annex II are power radiation and reception efficiencies for the transmitting and receiving antennas, respectively. With the frequencies and antenna heights usually considered for tropospheric communication circuits, these efficiencies are nearly unity and the difference between $L_s$ and $L$ is negligible. With antennas a fraction of a wavelength above ground, as they usually are at lower frequencies, and especially when horizontal polarization is used, $L_{et}$ and $L_{er}$ are not negligible, but are influenced substantially by the presence of the ground and other nearby portions of the antenna environment.

From transmitter output to receiver input, the following symbols are used:

<table>
<thead>
<tr>
<th>Transmitter Output Power</th>
<th>Power Input to Antenna</th>
<th>Total Power Radiated at Loss-Free Antenna Power</th>
<th>Available Power at Actual Receiving Antenna</th>
<th>Available Power at Receiver Input</th>
</tr>
</thead>
<tbody>
<tr>
<td>$W_{tt}$</td>
<td>$W_t$</td>
<td>$W_t$</td>
<td>$W_a$</td>
<td>$W_{fr}$.</td>
</tr>
<tr>
<td>$L_{lt}$</td>
<td>$L_{et}$</td>
<td>$L$</td>
<td>$L_{er}$</td>
<td>$L_{fr}$.</td>
</tr>
<tr>
<td>$L_s$</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

It should be noted that $L_{lt}$ and $L_{fr}$ are conceptually different. Since $W_{tt}$ and $W_t$ represent the power observed at the transmitter and at the transmitting antenna, respectively, $L_{lt}$ includes both transmission line and mismatch losses. Since $W_a$ and $W_{fr}$ represent available power at the receiving antenna and at the receiver, mismatch losses must be accounted for separately, since $L_{fr}$ includes only the transmission line loss between the antenna and the receiver. Available power and effective loss factors are discussed in annex II.
2.2 Antenna Directive Gain and Power Gain

A transmitting antenna has a directive gain \( g_t(\hat{r}) \) in the direction of a unit vector \( \hat{r} \) if:

1. it radiates a total of \( w_t \) watts through the surface of any large sphere with the antenna at its center, and
2. it radiates \( g_t w_t/(4\pi) \) watts per steradian in the direction \( \hat{r} \).

The same antenna has a power gain \( g'_t(\hat{r}) \) in the direction \( \hat{r} \) if:

1. the power input to the antenna terminals is \( w'_t = \frac{1}{\epsilon_t} w_t \), and
2. it radiates \( g'_t w'_t/(4\pi) \) watts per steradian in the direction \( \hat{r} \).

The antenna power gain \( g'_t \) is smaller than the directive gain \( g_t \) simply as a result of the loss factor \( \frac{1}{\epsilon_t} \). It follows that

\[
G_t(\hat{r}) = G'_t(\hat{r}) + L_{et} \tag{2.4a}
\]

expressed in decibels above the gain of an isotropic radiator. Note that the antenna power gain \( G'_t(\hat{r}) \) is less than the antenna directive gain \( G_t(\hat{r}) \) by the amount \( L_{et} \) dB, where the power radiation efficiency \( 1/\epsilon_t \) is independent of the direction \( \hat{r} \).

The gain of an antenna is the same whether it is used for transmitting or receiving.

For a receiving antenna, the directive gain \( G_r(\hat{r}) \) and power gain \( G'_r(\hat{r}) \) are related by

\[
G_r(\hat{r}) = G'_r(\hat{r}) + L_{er} \tag{2.4b}
\]

The remainder of this report will deal with directive gains, since the power gains may be determined simply by subtracting \( L_{et} \) or \( L_{er} \). The maximum value of a directive gain \( G(\hat{r}) \) is designated simply as \( G \). As noted in Annex II, it is sometimes useful to divide the directive gain into principal and cross-polarization components.

An idealized antenna in free space with a half-power semi-beamwidth \( \delta \) expressed in radians, and with a circular beam cross-section, may be assumed to radiate \( x \) percent of its power isotropically through an area equal to \( \pi \delta^2 \) on the surface of a large sphere of unit radius, and to radiate \((100-x)\) percent of its power isotropically through the remainder of the sphere. In this case the power radiated in the direction of the main beam is equal to \( xw_t/(100\pi\delta^2) \) watts per steradian and the maximum gain \( g \) is, by definition, equal to \( 4\pi x/(100\pi\delta^2) \). One may assume a beam solid angle efficiency \( x = 56 \) percent for parabolic reflectors with 10 db tapered illumination, and obtain \( g = 2.24/\delta^2 \). The maximum free space gain \( G \) in decibels relative to an isotropic radiator is then

\[
G = 10 \log g = 3.50 - 20 \log \delta \text{ db} \tag{2.5}
\]
If azimuthal and vertical beamwidths $\delta_w$ and $\delta_z$ are different:

$$\delta = \sqrt{\delta_w \delta_z}.$$  \hspace{1cm} (2.6)

The above analysis is useful in connection with measured antenna radiation patterns.

For antennas such as horns or parabolic reflectors which have a clearly definable physical aperture, the concept of antenna aperture efficiency is useful. For example, the free space maximum gain of a parabolic dish with a 56 percent aperture efficiency and a diameter $D$ is the ratio of 56 percent of its area to the effective absorbing area of an isotropic radiator:

$$G = 10 \log \left[ \frac{0.56 \pi D^2/4}{\lambda^2/4\pi} \right] = 20 \log D + 20 \log f - 42.10 \text{ db} \hspace{1cm} (2.7)$$

where $D$ and $\lambda$ are in meters and $f$ is the radio frequency in megahertz, MHz.

Equations (2.5) and (2.7) are useful for determining the gains of actual antennas only when their beam solid angle efficiencies or aperture efficiencies are known, and these can be determined accurately only by measurement.

With a dipole feed, for instance, and $10 < D/\lambda < 25$, experiments have shown the following empirical formula to be superior to (2.7):

$$G = 23.3 \log D + 23.3 \log f - 55.1 \text{ db} \hspace{1cm} (2.8)$$

where $D$ is expressed in meters and $f$ in MHz.

Cozzens [1962] has published a nomograph for determining paraboloidal maximum gain as a function of feed pattern and angular aperture. Discussions of a variety of commonly-used antennas are given in recent books [Jasik, 1961; Thourel, 1960].

Much more is known about the amplitude, phase, and polarization response of available antennas in the directions of maximum radiation or reception than in other directions. Most of the theoretical and developmental work has concentrated on minimizing the transmission loss between antennas and on studies of the response of an arbitrary antenna to a standard plane wave. An increasing amount of attention, however, is being devoted to maximizing the transmission loss between antennas in order to reject unwanted signals. For this purpose it is important to be able to specify, sometimes in statistical terms, the directivity, phase, and polarization response of an antenna in every direction from which multipath components of each unwanted signal may be expected. A large part of annex II is devoted to this subject.

For the frequencies of interest in this report, antenna radiation resistances $r_v$ at any radio frequency $v$ hertz are usually assumed independent of their environment, or else the immediate environment is considered part of the antenna, as in the case of an antenna mounted on an airplane or space vehicle.
2.3 Polarization Coupling Loss and Multipath Coupling Loss

It is sometimes necessary to minimize the response of a receiving antenna to unwanted signals from a single source by way of different paths. This requires attention to the amplitudes, polarizations, and relative phases of a number of waves arriving from different directions. In any theoretical model, the phases of principal and cross-polarization components of each wave, as well as the relative phase response of the receiving antenna to each component, must be considered. Complex voltages are added at the antenna terminals to make proper allowance for this amplitude and phase information.

In annex II it is shown how complex vectors \( \mathbf{e} \) and \( \mathbf{e}_r \) may be used to represent transmitting and receiving antenna radiation and reception patterns which will contain amplitude, polarization, and phase information [Kales, 1951] for a given free-space wavelength, \( \lambda \). A bar is used under the symbol for a complex vector \( \mathbf{e} = \mathbf{e}_p + i \mathbf{e}_c \), where \( i = \sqrt{-1} \) and \( \mathbf{e}_p, \mathbf{e}_c \) are real vectors which may be associated with principal and cross-polarized components of a uniform elliptically polarized plane wave.

Calculating the power transfer between two antennas in free space, complex polarization vectors \( \mathbf{e}(\mathbf{r}) \) and \( \mathbf{e}_r(-z) \) are determined for each antenna as if it were the transmitter and the other were the receiver. Each antenna must be in the far field or radiation field of the other. The sense of polarization of the field \( \mathbf{e} \) is right-handed or left-handed depending on whether the axial ratio of the polarization ellipse, \( a_x \), is positive or negative:

\[
a_x = \frac{e_c}{e_p},
\]

The polarization is circular if \( |e_p| = |e_c| \) and linear if \( e_c = 0 \), where \( e = e_p e_c^{\prime} \) is in the principal polarization direction defined by the unit vector \( e_p \). The polarization coupling loss in free space is

\[
L_{cp} = -10 \log |\mathbf{e}_p \cdot \mathbf{e}_r|^2 \text{ dB},
\]

In terms of the axial ratios \( a_x \) and \( a_{xr} \) defined by (II. 48) and (II. 50) and the acute angle \( \psi \) between principal polarization vectors \( e_p \) and \( e_{pr} \), the corresponding polarization efficiency may be written as

\[
|\mathbf{e}_p \cdot \mathbf{e}_r|^2 = \frac{\cos^2 \psi (a_{x} a_{xr} + 1)^2 + \sin^2 \psi (a_{x} + a_{xr})^2}{(a_x + 1)(a_{xr} + 1)}.
\]

This is the same as (II. 62). Annex II explains how these definitions and relationships are extended to the general case where antennas are not in free space.

There is a maximum transfer of power between two antennas if the polarization ellipse of the receiving antenna has the same sense, eccentricity, and principal polarization direction as the polarization ellipse of the incident radio wave. The receiving antenna is completely "blind" to the incident wave if the sense of polarization is opposite,
the eccentricity is the same, and the principal polarization direction is orthogonal to that of the incident wave. In theory this situation would result in the complete rejection of an unwanted signal propagating in a direction \(-\hat{r}\). Small values of \(g(\hat{r})\) could at the same time discriminate against unwanted signals coming from other directions.

When more than one plane wave is incident upon a receiving antenna from a single source, there may be a "multipath coupling loss" which includes beam orientation, polarization coupling, and phase mismatch losses. A statistical average of phase incoherence effects, such as that described in subsection 9.4, is called "antenna-to-medium coupling loss." Multipath coupling loss is the same as the "loss in path antenna gain," \(L_{gp}\), defined in the next subsection. Precise expressions for \(L_{gp}\) may also be derived from the relationships in annex II.
2.4 Path Loss, Basic Transmission Loss, Path Antenna Gain, and Attenuation Relative to Free Space

Recorded values of transmission loss are often normalized to "path loss" by adding the sum of the maximum free space gains of the antennas, $G_t + G_r$, to the transmission loss, $L$. Path loss is defined as

$$L_p = L + G_t + G_r \text{ dB} \quad (2.12)$$

Basic transmission loss, $L_b$, is the system loss for a situation where the actual antennas are replaced at the same locations by hypothetical antennas which are:

1. Isotropic, so that $G_t(\hat{r}) = 0 \text{ dB}$ and $G_r(-\hat{r}) = 0 \text{ dB}$ for all important propagation directions, $\hat{r}$.
2. Loss-free, so that $L_{et} = 0 \text{ dB}$ and $L_{er} = 0 \text{ dB}$.
3. Free of polarization and multipath coupling loss, so that $L_{cp} = 0 \text{ dB}$.

If the maximum antenna gains are realized, $L_0 = L_b$.

Corresponding to this same situation, the path antenna gain, $G_p$, is defined as the change in the transmission loss if hypothetical loss-free isotropic antennas with no multipath coupling loss were used at the same locations as the actual antennas. Assumptions used in estimating $G_p$ should always be carefully stated.

Replace both antennas by loss-free isotropic antennas at the same locations, with no coupling loss between them and having the same radiation resistances as the actual antennas, and let $W_{ab}$ represent the resulting available power at the terminals of the hypothetical isotropic receiving antenna. Then the basic transmission loss $L_b$, the path antenna gain $G_p$, and the path antenna power gain $G_{pp}$, are given by

$$L_b = W_t - W_{ab} = L + G_p \text{ dB} \quad (2.13)$$

$$G_p = W_a - W_{ab} = L_b - L \text{ dB} \quad (2.14a)$$

$$G_{pp} = W'_a - W'_{ab} = L_b - L_s \text{ dB} \quad (2.14b)$$

where $W_t$, $W_a$, $W'_a$ and $L_s$ are defined in section 2.1.

In free space, for instance:

$$W_a = W_t + G_t(\hat{r}) + G_r(-\hat{r}) - L_{cp} + 20 \log \left( \frac{\lambda}{4\pi r} \right) \text{ dbw} \quad (2.15a)$$

$$W_{ab} = W_t + 20 \log \left( \frac{\lambda}{4\pi r} \right) \text{ dbw} \quad (2.15b)$$

A special symbol, $L_{bf}$, is used to denote the corresponding basic transmission loss in free space:

$$L_{bf} = 20 \log \left( \frac{4\pi r}{\lambda} \right) = 32.45 + 20 \log f + 20 \log r \text{ dB} \quad (2.16)$$
where the antenna separation $r$ is expressed in kilometers and the free space wavelength $\lambda$ equals $0.2997925/f$ kilometers for a radio frequency $f$ in megahertz.

When low gain antennas are used, as on aircraft, the frequency dependence in (2.16) indicates that the service range for UHF equipment can be made equal to that in the VHF band only by using additional power in direct proportion to the square of the frequency. Fixed point-to-point communications links usually employ high-gain antennas at each terminal, and for a given antenna size more gain is realized at UHF than at VHF, thus more than compensating for the additional free space loss at UHF indicated in (2.16).

Comparing (2.13), (2.14), and (2.15), it is seen that the path antenna gain in free space, $G_{pf}$, is

$$G_{pf} = G_t(\hat{f}) + G_r(-\hat{f}) - L_{cp} \text{ db. (2.17)}$$

For most wanted propagation paths, this is well approximated by $G_t + G_r$, the sum of the maximum antenna gains. For unwanted propagation paths it is often desirable to minimize $G_{pf}$. This can be achieved not only by making $G_t(\hat{f})$ and $G_r(-\hat{f})$ small, but also by using different polarizations for receiving and transmitting antennas so as to maximize $L_{cp}$.

In free space the transmission loss is

$$L = L_{bf} - G_{pf} \text{ db. (2.18)}$$

The concepts of basic transmission loss and path antenna gain are also useful for normalizing the results of propagation studies for paths which are not in free space. Defining an "equivalent free-space transmission loss", $L_f$, as

$$L_f = L_{bf} - G_p \text{ db. (2.19)}$$

note that $G_p$ in (2.19) is not equal to $G_t + G_r$ unless this is true for the actual propagation path. It is often convenient to investigate the "attenuation relative to free space", $A$, or the basic transmission loss relative to that in free space, defined here as

$$A = L_b - L_{bf} = L - L_f \text{ db. (2.20)}$$

This definition, with (2.19), makes $A$ independent of the path antenna gain, $G_p$. Where terrain has little effect on line-of-sight propagation, it is sometimes desirable to study $A$ rather than the transmission loss, $L$.

Although $G_p$ varies with time, it is customary to suppress this variation [Hartman, 1963] and to estimate $G_p$ as the difference between long-term median values of $L_b$ and $L$.

Multipath coupling loss, or the "loss in path antenna gain", $G_{gp}$, is defined as the difference between path loss $L_o$ and basic transmission loss $L_{bf}$.
The loss in path antenna gain will therefore, in general, include components of beam orientation loss and polarization coupling loss as well as any aperture-to-medium coupling loss that may result from scattering by the troposphere, by rough or irregular terrain, or by terrain clutter such as vegetation, buildings, bridges, or power lines.

The relationships between transmission loss, propagation loss and field strength are discussed in annex II.
3. ATMOSPHERIC ABSORPTION

At frequencies above 2 GHz, attenuation of radio waves due to absorption or scattering by constituents of the atmosphere, and by particles in the atmosphere, may seriously affect microwave relay links, communication via satellites, and radio and radar astronomy. At frequencies below 1 GHz, the total radio wave absorption by oxygen and water vapor for propagation paths of 1000 kilometers or less will not exceed 2 decibels. Absorption by rainfall begins to be barely noticeable at frequencies from 2 to 3 GHz, but may be quite appreciable at higher frequencies.

For frequencies up to 100 GHz, and for both optical and transhorizon paths, this section provides estimates of the long-term median attenuation $A_a$ of radio waves by oxygen and water vapor, the attenuation $A_r$ due to rainfall, and the order of magnitude of absorption by clouds of a given water content. The estimates are based on work reported by Artman and Gordon [1954], Bean and Abbott [1957], Bussey [1950], Crawford and Hogg [1956], Gunn and East [1954], Hathaway and Evans [1959], Hogg and Mumford [1960], Hogg and Semplak [1961], Lane and Saxton [1952], Laws and Parsons [1943], Perlat and Voge [1953], Straiton and Tolbert [1960], Tolbert and Straiton [1957], and Van Vleck [1947a, b; 1951].

3.1 Absorption by Water Vapor and Oxygen

Water vapor absorption has a resonant peak at a frequency of 22.23 GHz, and oxygen absorption peaks at a number of frequencies from 53 to 66 GHz and at 120 GHz. Figure 3.1, derived from a critical appraisal of the above references, shows the differential absorption $\gamma_{oo}$ and $\gamma_{wo}$ in decibels per kilometer for both oxygen and water vapor, as determined for standard conditions of temperature and pressure and for a surface value of absolute humidity equal to 10 grams per cubic meter. These values are consistent with those prepared for the Xth Plenary Assembly of the CCIR by U.S. Study Group IV [1963d] except that the water vapor density is there taken to be 7.5 g/m$^3$. For the range of absolute humidity likely to occur in the atmosphere, the water vapor absorption in db/km is approximately proportional to the water vapor density.

The total atmospheric absorption $A_a$ decibels for a path of length $r_o$ kilometers is commonly expressed in one of two ways, either as the integral of the differential absorption $\gamma(r)$ dr:

$$A_a = \int_0^{r_o} \gamma(r) \, dr \, \text{db} \quad (3.1)$$

or in terms of an absorption coefficient $\Gamma(r)$ expressed in reciprocal kilometers:

$$A_a = -10 \log \exp \left( -\int_0^{r_o} \Gamma(r) \, dr \right) = 4.343 \int_0^{r_o} \Gamma(r) \, dr \, \text{db} \quad (3.2)$$

3-1
The argument of the logarithm in (3.2) is the amount of radiowave energy that is not absorbed in traversing the path.

The total gaseous absorption $A_a$ over a line-of-sight path of length $r_o$ kilometers is

$$A_a = \int_0^r dr \left[ \gamma_o(h) + \gamma_w(h) \right] \text{ db}$$

(3.3)

where $h$ is the height above sea level at a distance $r$ from the lower terminal, measured along a ray path between terminals. For radar returns, the total absorption is $2A_a$ db.

Considering oxygen absorption and water vapor absorption separately, (3.3) may be written

$$A_a = \gamma_{eo} r_{eo} + \gamma_{ew} r_{ew} \text{ db}$$

(3.4)

where $r_{eo}$ and $r_{ew}$ are effective distances obtained by integrating $\gamma_o/\gamma_{eo}$ and $\gamma_w/\gamma_{ew}$ over the ray path.

The effective distances $r_{eo}$ and $r_{ew}$ are plotted versus $r_0$ and frequency for elevation angles $\theta_0 = 0$, $0.01$, $0.02$, $0.05$, $0.1$, $0.2$, $0.5$, $1$, and $\pi/2$ radians in figures 3.2-3.4. Figure 3.5 shows the relationship between $r_0$ and the sea level arc distance, $d$, for these values of $\theta_0$.

$A_a$ may be estimated from figures 1.21 to 1.26 of annex I, where attenuation relative to free space, $A$, is plotted versus $f$, $\theta_0$, and $r_0$, ignoring effects of diffraction by terrain.

For nonoptical paths, the ray from each antenna to its horizon makes an angle $\theta_{ot}$ or $\theta_{or}$ with the horizontal at the horizon, as illustrated in figure 6.1 of section 6. The horizon rays intersect at distances $d_1$ and $d_2$ from the transmitting and receiving terminals. The total absorption $A_a$ is the sum of values $A_{at}$ and $A_{ar}$

$$A_a = A_{at} + A_{ar}$$

(3.5)

where

$$A_{at} = A_a (f, \theta_{ot}, d_1) \quad A_{ar} = A_a (f, \theta_{or}, d_2)$$

For propagation over a smooth earth, $\theta_0 = \theta_{ot} = 0$, and $A = 2A_a (f, 0, d/2)$. For trans-horizon paths and the frequency range $0.1 - 10$ GHz, figure 3.6 shows $A_a$ plotted versus distance over a smooth earth between 10 meter antenna heights.
3.2 Sky-Noise Temperature

The non-ionized atmosphere is a source of radio noise, with the same properties as a reradiator that it has as an absorber. The effective sky-noise temperature $T_s$ may be determined by integrating the gas temperature $T$ multiplied by the differential fraction of reradiated power that is not absorbed in passing through the atmosphere to the antenna:

$$T_s(°K) = \int_0^\infty T(r)\Gamma(r) \exp \left[ -\int_0^r \Gamma(r') \, dr' \right] \, dr \tag{3.6}$$

where the absorption coefficient $\Gamma(r)$ in reciprocal kilometers is defined by (3.2). For instance, assuming

$$T(r) = (288 - 6.5h)°K \quad \text{for} \quad h \leq 12 \text{ km},$$

and

$$T(r) = 210°K \quad \text{for} \quad h \geq 12 \text{ km},$$

figure 3.7 shows the sky-noise temperature due to oxygen and water vapor for various angles of elevation and for frequencies between 0.1 and 100 GHz.

In estimating antenna temperatures, the antenna pattern and radiation from the earth's surface must also be considered.
3.3 Attenuation by Rain

The attenuation of radio waves by suspended water droplets and rain often exceeds the combined oxygen and water vapor absorption. Water droplets in fog or rain will scatter radio waves in all directions whether the drops are small compared to the wavelength or comparable to the wavelength. In the latter case, raindrops trap and absorb some of the radio wave energy; accordingly, rain attenuation is much more serious at millimeter wavelengths than at centimeter wavelengths.

In practice it has been convenient to express rain attenuation as a function of the precipitation rate $R_r$ which depends on both the liquid water content and the fall velocity of the drops, the latter in turn depending on the size of the drops. There is little evidence that rain with a known rate of fall has a unique drop-size distribution, and the problem of estimating the attenuation of radio waves by the various forms of precipitation is quite difficult.

Total absorption $A_r$ due to rainfall over a path of length $r_o$ can be estimated by integrating the differential rain absorption $\gamma_r(r) \, dr$ along the direct path between two intervisible antennas, or along horizon rays in the case of transhorizon propagation:

$$A_r = \int_0^r \gamma_r(r) \, dr \text{ decibels.} \tag{3.7}$$

Fitting an arbitrary mathematical function empirically to theoretical results given by Hathaway and Evans [1959] and Ryde and Ryde [1945], the rate of absorption by rain $\gamma_r$ may be expressed in terms of the rainfall rate $R_r$ in millimeters per hour as

$$\gamma_r = KR_r^{\sigma} \text{ db/km} \tag{3.8}$$

for frequencies above 2 GHz. The functions $K(f_G)$ and $\sigma(f_G)$ are plotted in figures 3.8 and 3.9, where $f_G$ is the radio frequency in GHz.

$$K = \left[ 3(f_G - 2)^2 - 2(f_G - 2) \right] \times 10^{-4} \tag{3.9a}$$

$$\sigma = [1.14 - 0.07(f_G - 2)^1] \left[ 1 + 0.085(f_G - 3.5) \exp(-0.006 f_G^2) \right]. \tag{3.9b}$$

An examination of the variation of rainfall rate with height suggests a relation of the form

$$\frac{R_r}{R_{rs}} = \exp(-0.2 h^1) \tag{3.10}$$
where \( R_{rs} \) is the surface rainfall rate. Then

\[
A_r = \gamma_{rs} r_{er} \text{ db,} \tag{3.11}
\]

\[
\gamma_{rs} = K R_{rs}^2 \text{ db/km,} \quad r_{er} = \int_0^{r_o} \text{dr} \exp(-0.2 a h^2) \text{ km} \tag{3.12}
\]

where \( \gamma_{rs} \) is the surface value of the rate of absorption by rain, and \( r_{er} \) is an "effective rainbearing distance". Figures 3.10-3.13 show \( r_{er} \) versus \( r_o \) for several values of \( h \) and \( \alpha \). The curves shown were computed using (3.12).

A "standard" long-term cumulative distribution of rain absorption is estimated, using some statistics from Ohio analyzed by Bussey [1950], who relates the cumulative distribution of instantaneous path average rainfall rates for 25, 50, and 100-kilometer paths, respectively, with the cumulative distributions for a single rain gauge of half-hour, one-hour, and two-hour mean rainfall rates, recorded for a year. The total annual rainfall in Ohio is about 110 centimeters.

Rainfall statistics vary considerably from region to region, sometimes from year to year, and often with the direction of a path (with or across prevailing winds). For instance, in North America, east-west systems seem particularly vulnerable, as they lie along the path of frequent heavy showers.

For very long paths, the cumulative distribution of instantaneous path average rainfall rates, \( \overline{R_r} \), depends on how \( R_r \) varies with elevation above the surface and upon the correlation of rainfall with distance along the path. Figure 3.14 provides estimates of the instantaneous path average rainfall rate \( \overline{R_r} \) exceeded for 0.01, 0.1, 1, and 5 percent of the year as a function of \( r_{er} \) and normalized to a total annual rainfall of 100 cm. To obtain \( A_r \) from (3.11), replace \( R_{rs} \) in (3.12) with \( \overline{R_r} \) from figure 3.14, multiplied by the ratio of the total annual rainfall and 100 cm. These estimates are an extrapolation of the results given by Bussey [1950] and are intended to allow for the average variation of \( R_r \) with height, as given by (3,10) and allowed for in the definition of \( r_{er} \), and for the correlation of surface rainfall rate \( R_{rs} \) with distance along the surface, as analyzed by Bussey.
3.4 Attenuation in Clouds

Cloud droplets are regarded here as those water or ice particles having radii smaller than 100 microns or 0.01 cm. Although a rigorous approach to the problem of attenuation by clouds must consider drop-size distribution, it is more practical to speak of the water content of clouds rather than the drop-size distribution. Reliable measurements of both parameters are scarce, but it is possible to make reasonable estimates of the water content, \( M \), of a cloud from a knowledge of the vertical extent of the cloud and the gradients of pressure, temperature, and mixing ratio, which is the ratio of the mass of water vapor to the mass of dry air in which it is mixed. The absorption within a cloud can be written as

\[
A = K M \text{ db}
\]

where \( A \) is the total absorption attenuation within the cloud, \( K \) is an attenuation coefficient, values for which are given in Table 3.1, and \( M \) is the liquid water content of the cloud, measured in grams per cubic meter. The amount of precipitable water, \( M \), in a given pressure layer can be obtained by evaluating the average mixing ratio in the layer, multiplying by the pressure difference, and dividing by the gravity. Using this method of obtaining \( M \) and the values of \( K \) from Table 3.1, it is possible to get a fairly reliable estimate of the absorption of radio energy by a cloud.

Several important facts are demonstrated by Table 3.1. The increase in attenuation with increasing frequency is clearly shown. The values change by about an order of magnitude from 10 to 30 GHz. Cloud attenuation can be safely neglected below 6 GHz. The data presented here also show that attenuation increases with decreasing temperature. These relations are a reflection of the dependence of the refractive index on both wavelength and temperature. The different dielectric properties of water and ice are illustrated by the difference in attenuation. Ice clouds give attenuations about two orders of magnitude smaller than water clouds of the same water content.

Figure 3.13
PATH AVERAGE RAINFALL RATE, $R_r$, vs EFFECTIVE RAINBEARING DISTANCE, $r_e$ (TOTAL ANNUAL RAINFALL, 100 cm)

Figure 3.14
4. DETERMINATION OF AN EFFECTIVE EARTH'S RADIUS

The bending of a radio ray as it passes through the atmosphere is largely determined by the gradient of the refractive index near the earth's surface. In order to represent radio rays as straight lines, at least within the first kilometer above the surface, an "effective earth's radius" is defined as a function of the refractivity gradient, $\Delta N$, or of the surface refractivity value $N_s$,

$$N_s = (n_s - 1) \times 10^6$$  \hspace{1cm} (4.1)

where $n_s$ is the atmospheric refractive index at the surface of the earth.

In the United States the following empirical relationship has been established between the mean $N_s$ and the mean refractivity gradient $\Delta N$ in the first kilometer above the surface:

$$\Delta N/\text{km} = -7.32 \exp(0.005577 N_s).$$  \hspace{1cm} (4.2)

Similar values have been established in West Germany and in the United Kingdom [CCIR 1963e]. In this paper values of $N_s$ are used to characterize average atmospheric conditions during periods of minimum field strength. In the northern temperate zone, field strengths and values of $N_s$ reach minimum values during winter afternoons. Throughout the world, regional changes in expected values of transmission loss depend on minimum monthly mean values of a related quantity, $N_o$, which represents surface refractivity reduced to sea level:

$$N_s = N_o \exp(-0.1057 h_s)$$  \hspace{1cm} (4.3)

where $h_s$ is the elevation of the surface above mean sea level, in kilometers, and the refractivity $N_o$ is read from the map shown in figure 4.1 and taken from Bean, Horn, and Ozanich [1960].

Most of the refraction of a radio ray takes place at low elevations, so it is appropriate to determine $N_o$ and $h_s$ for locations corresponding to the lowest elevation of the radio rays most important to the geometry of a propagation path. As a practical matter for within-the-horizon paths, $h_s$ is defined as the ground elevation immediately below the lower antenna terminal, and $N_o$ is determined at the same location. For beyond-the-horizon paths, $h_s$ and $N_o$ are determined at the radio horizons along the great circle path between the antennas, and $N_s$ is the average of the two values calculated from (4.3). An exception to this latter rule occurs if an antenna is more than 150 meters below its radio horizon; in such a case, $h_s$ and $N_o$ should be determined at the antenna location.

The effective earth's radius, $a$, is given by the following expression:

$$a = a_o [1 - 0.04665 \exp(0.005577 N_s)]^{-1}$$  \hspace{1cm} (4.4)
where \( a_0 \) is the actual radius of the earth, and is taken to be 6370 kilometers. Figure 4.2 shows the effective earth's radius, \( a \), plotted versus \( N_0 \). The total bending of a radio ray which is elevated more than 0.785 radians (45°) above the horizon and which passes all the way through the earth's atmosphere is less than half a milliradian. For studies of earth-satellite communication ray bending is important at low angles. At higher angles it may often be neglected and the actual earth's radius is then used in geometrical calculations.

Large values of \( \Delta N \) and \( N_0 \) are often associated with atmospheric ducting, which is usually important for part of the time over most paths, especially in maritime climates. The average occurrence of strong layer reflections, superrefraction, ducting, and other focusing and defocusing effects of the atmosphere is taken into account in the empirical time variability functions to be discussed in section 10. Additional material on ducting will be found in papers by Anderson and Gossard [1953a, b], Bean [1959], Booker [1946], Booker and Walkinshaw [1946], Clemow and Bruce-Clayton [1963], Dutton [1961], Fok, Vainshtein, and Belkina [1958], Friend [1945], Hay and Unwin [1952], Ikegami [1959], Kitchen, Joy, and Richards [1958], Nomura and Takaku [1955], Onoe and Nishikori [1957], Pekeris [1947], Schüinemann [1957], and Unwin [1953].

5. TRANSMISSION LOSS PREDICTION METHODS FOR WITHIN-THE-HORIZON PATHS

Ground wave propagation over a smooth spherical earth of uniform ground conductivity and dielectric constant, and with a homogeneous atmosphere, has been studied extensively. Some of the results were presented in CCIR Atlases [1955, 1959]. Recent work by Bachynski [1959, 1960, 1963], Wait [1963], Furutsu [1963], and others considers irregularities of electrical ground constants and of terrain. A distinction is made here between the roughness of terrain which determines the proportion between specular and diffuse reflection of radio waves, and large scale irregularities whose average effect is accounted for by fitting a straight line or curve to the terrain.

A comprehensive discussion of the scattering of electromagnetic waves from rough surfaces is given in a recent book by Beckmann and Spizzichino [1963]. Studies of reflection from irregular terrain as well as absorption, diffraction, and scattering by trees, hills, and man-made obstacles have been made by Beckmann [1957], Biot [1957a, b], Kallmünz [1957, 1958], Kühn [1958], McGavin and Maloney [1959], McPetrie and Ford [1946], McPetrie and Saxton [1942], Saxton and Lane [1955], Sherwood and Ginzton [1955], and many other workers. Examples of studies of reflection from an ocean surface may be found in papers by Beard, Katz and Spetner [1956], and Beard [1961].

A semi-empirical method for predicting transmission loss for within-the-horizon paths is given in annex I.

Reflections from hillsides or obstacles off the great circle path between two antennas sometimes contribute a significant amount to the received signal. Discrimination against such off-path reflections may reduce multipath fading problems, or in other cases antenna beams may be directed away from the great circle path in order to increase the signal level by taking advantage of off-path reflection or knife-edge diffraction. For short periods of time, over some paths, atmospheric focusing or defocusing will lead to somewhat smaller or much greater values of line-of-sight attenuation than the long-term median values predicted for the average path by the methods of this section.

If two antennas are intervisible over the effective earth defined in section 4, ray optics may be used to estimate the attenuation \( A \) relative to free space, provided that the great circle path terrain visible to both antennas will support a substantial amount of reflection and that it is reasonable to fit a straight line or a convex curve of radius \( a \) to this portion of the terrain.
5.1 Line-of-Sight Propagation Over Irregular Terrain

Where ray optics formulas, described in section 5.2, are not applicable a satisfactory estimate of line-of-sight transmission loss may sometimes be made by one of the following methods:

1. If a slight change in the position of either antenna results in a situation where ray optics formulas may be used, then $A$ may be estimated by extrapolation or interpolation.

2. Instead of a single curve fit to terrain as in 5.2 the method may, in some cases, be extended to multiple curve fits and multiple reflections from these curves.

3. If terrain is so irregular it cannot be reasonably well approximated by a single curve, the line-of-sight knife-edge formulas of section 7 may be applicable.

4. Interpolation between curves in an atlas, or standard propagation curves such as those given in appendix I, may provide a satisfactory estimate. A useful set of calculations for $\theta = 0$ is given by Domb and Pryce [1947].

5. Empirical curves drawn through data appropriate for the problem of interest may be useful. For example, the dashed curves of figures I.1-I.3 show how values of attenuation relative to free space vary with distance and frequency for a large sample of recordings of television signals over random paths. The data shown in figures I.1-I.4 correspond to a more careful selection of receiving locations and to a greater variety of terrain and climatic conditions.
5.2 Line-of-Sight Propagation Over a Smooth or Uniformly Rough Spherical Earth

The simplest ray optics formulas assume that the field at a receiving antenna is made up to two components, one associated with a direct ray having a path length \( r_0 \), and the other associated with a ray reflected from a point on the surface, with equal grazing angles \( \psi \). The reflected ray has a path length \( r_1 + r_2 \). The field arriving at the receiver via the direct ray differs from the field arriving via the reflected ray by a phase angle which is a function of the path length difference, \( \Delta r = r_1 + r_2 - r_0 \), illustrated in figure 5.1. The reflected ray field is also modified by an effective reflection coefficient \( R_e \) and associated phase lag \((\pi - c)\), which depend on the conductivity, permittivity, roughness, and curvature of the reflecting surface, as well as upon the ratio of the products of antenna gain patterns in the directions of direct and reflected ray paths.

Let \( g_{01} \) and \( g_{02} \) represent the directive gain for each antenna in the direction of the other, assuming antenna polarizations to be matched. Similar factors \( g_{r1} \) and \( g_{r2} \) are defined for each antenna in the direction of the point of ground reflection. The effective reflection coefficient \( R_e \) is then

\[
R_e = D R \left( \frac{g_{r1} g_{r2}}{g_{01} g_{02}} \right)^{1/2} \exp \left( \frac{-0.6 \sigma_h \sin \psi}{\lambda} \right)
\]  

(5.1)

where the divergence factor \( D \) allows for the divergence of energy reflected from a curved surface, and may be approximated as

\[
D = \left[ 1 + \frac{2d_1 d_2}{\lambda \tan \psi} \right]^{1/2}
\]

(5.2)

A more exact expression for the divergence factor, \( D \), based on geometric optics was derived by Riblet and Barker [1948]. The term \( R \) represents the magnitude of the theoretical coefficient, \( R \exp[-i(\pi - c)] \), for reflection of a plane wave from a smooth plane surface of a given conductivity and dielectric constant. In most cases \( c \) may be set equal to zero and \( R \) is very nearly unity. A notable exception for vertical polarization over sea water is discussed in annex III. Values of \( R \) and \( c \) vs \( \psi \) are shown on figures III.1 to III.8 for both vertical and horizontal polarization over good, average, and poor ground, and over sea water.

The grazing angle \( \psi \) and the other geometrical parameters \( d, d_1, d_2, \) and \( a \) are shown on figure 5.1. The terrain roughness factor, \( \sigma_h \), defined in section 5.2.2, and the radio wave length, \( \lambda \), are expressed in the same units. The exponent \( (\sigma_h \sin \psi)/\lambda \) is Rayleigh's criterion of roughness.
If the product $DR \exp(-0.6 \sigma_h \sin \psi/\lambda)$ is less than $\sqrt{\sin \psi}$, and is less than 0.5, ground reflection may be assumed to be entirely diffuse and $R_e$ is then expressed as

$$R_e = \left[ \frac{g_{r1} g_{r2}}{g_{01} g_{02}} \sin \psi \right]^{1/2} \quad (5.3)$$

where terrain factors $D, R$ and $\sigma_h$ are ignored. The factor $g_{r1} g_{r2} / g_{01} g_{02}$ in (5.3) makes $R_e$ approach zero when narrow-beam antennas are used to discriminate against ground reflections.

For a single ground reflection, the attenuation relative to free space may be obtained from the general formula

$$A = -10 \log \left[ g_{r1} g_{r2} \left( 1 + R_e^2 - 2R_e \cos \left( \frac{2\pi \Delta r}{\lambda} - \theta \right) \right) \right] + G_p + A_a \quad (5.4)$$

where the path antenna gain $G_p$ may not be equal to the sum of the maximum antenna gains. Losses $A_a$ due to atmospheric absorption, given by (3.4), may be important at frequencies above 1 GHz. The basic transmission loss $L_b$ is

$$L_b = 32.45 + 20 \log f + 20 \log r + A \quad (5.5)$$

Over a smooth perfectly-conducting surface, $R_e = 1$ and $c = 0$. Assuming also that free space antenna gains are realized, so that $G_p = 10 \log (g_{r1} g_{r2})$, the attenuation relative to free space is

$$A = -6 - 10 \log \sin^2 \left( \frac{\pi \Delta r}{\lambda} \right) \quad (5.6)$$

Exact formulas for computing $\Delta r$ are given in annex III. The appropriate approximations given in (5.9) to (5.13) suffice for most practical applications. If $\Delta r$ is less than 0.12$\lambda$, (5.4) may underestimate the attenuation and one of the methods of section 5.1 should be used.

Section 5.2.1 shows how to define antenna heights $h_1'$ and $h_2'$ above a plane earth, or above a plane tangent to the earth at the point of reflection. The grazing angle $\psi$ is then defined by

$$\tan \psi = \frac{h_1'}{d_1} = \frac{h_2'}{d_2} \quad (5.7)$$

where heights and distances are in kilometers and $d_1$ and $d_2$ are distances from each antenna to the point of specular reflection.
\[ d_1 + d_2 = d, \quad d_1 = d(1 + h'_1/h'_2)^{-1}, \quad d_2 = d(1 + h'_2/h'_1)^{-1}, \tag{5.8a} \]

The distances \( d_1 \) and \( d_2 \) may be approximated for a spherical earth by substituting antenna heights \( h_1 \) and \( h_2 \) above the earth for the heights \( h'_1 \) and \( h'_2 \) in (5.8a). Then these heights may be calculated as

\[ h'_1 = h_1 - d_1^2/(2a), \quad h'_2 = h_2 - d_2^2/(2a) \tag{5.8b} \]

for an earth of effective radius \( a \), and substituted in (5.8a) to obtain improved estimates of \( d_1 \) and \( d_2 \). Iterating between (5.8a) and (5.8b), any desired degree of accuracy may be obtained.

The path length difference between direct and ground reflected rays is

\[ \Delta r = \sqrt{d^2 + \left( h'_1 + h'_2 \right)^2} - \sqrt{d^2 + \left( h'_1 - h'_2 \right)^2} \approx 2 h'_1 h'_2/d \tag{5.9} \]

where the approximation in (5.9) is valid for small grazing angles.

Referring to (5.5) the greatest distance, \( d_o \), for which \( \Delta r \) is zero, (assuming that \( R = 1 \) and that free space gains are realized) occurs when \( \Delta r = \lambda/6 \). From (5.9)

\[ \Delta r \approx 2 h'_1 h'_2/d; \text{ therefore:} \]

\[ d_o = 12 h'_1 h'_2/\lambda. \tag{5.10a} \]

This equation may be solved graphically, or by iteration, choosing a series of values for \( d_o \), solving (5.8) for \( h'_1, h'_2 \), and testing the equality in (5.10a).

For the special case of equal antenna heights over a spherical earth of radius \( a \), the distance \( d_o \) may be obtained as follows:

\[ \Delta r = \lambda/6 = \frac{2}{d_o} \left[ h - d_o^2/(8a) \right]^2 = 2 h^2/d_o - h d_o/(2a) + d_o^3/(32a^2) \tag{5.10b} \]

where

\[ d_1 = d_2 = d/2, \quad h_1 = h_2 = h, \quad \text{and} \quad h' = h - d_o^2/(8a). \]
For this special case where \( h_1 = h_2 \) over a smooth spherical earth of radius \( a \), the angle \( \psi \) may be defined as

\[
\tan \psi = \frac{2 h}{d} - \frac{d}{4a}
\]

(5.11a)

and

\[
\Delta r = d (\sec \psi - 1) = d \left[ \sqrt{1 + \tan^2 \psi} - 1 \right].
\]

(5.11b)

Let \( \theta_h \) represent the angle of elevation of the direct ray \( r_o \) relative to the horizontal at the lower antenna, \( h_1 \), assume that \( h_1 < h_2 \), \( h_1 < 9a \psi^2 / 2 \), and that the grazing angle, \( \psi \), is small; then, over a spherical earth of effective radius \( a \),

\[
\Delta r \equiv 2 h_1 \sin \psi \equiv h_1 \left[ \sqrt{\frac{\theta_h^2}{h} + \frac{4h_1}{3a} + \theta_h} \right]
\]

(5.12)

whether \( \theta_h \) is positive or negative. For \( \theta_h = 0 \), \( d_1 \approx 2h_1/(3\psi) \).

Two very useful approximations for \( \Delta r \) are

\[
\Delta r \approx 2 \psi^2 d_1 d_2 / d \equiv 2h_1 \sin \psi \text{ kilometers}
\]

(5.13)

and the corresponding expressions for the path length difference in electrical radians and in electrical degrees are

\[
2\pi \Delta r / \lambda = 41.917 f h_1 h_2 / d = 41.917 f \psi^2 d_1 d_2 / d \equiv 42 f h_1 \sin \psi \text{ radians}
\]

(5.14a)

\[
360 \Delta r / \lambda = 2401.7 f h_1 h_2 / d = 2401.7 f \psi^2 d_1 d_2 / d \equiv 2402 f h_1 \sin \psi \text{ degrees}
\]

(5.14b)

where \( f \) is the radio frequency in MHz and all heights and distances are in kilometers.

The last approximation in (5.13) should be used only if \( h_1 \) is small and less than \( h_2 / 20 \), as it involves neglecting \( d_2^2 / (2a) \) relative to \( h_1 \) in (5.8) and assuming that \( d_2 \approx d \).

As noted following (5.5), ray optics formulas are limited to grazing angles such that

\( \Delta r > 0.06\lambda \). With this criterion, and assuming \( R = 1 \), the attenuation \( A \) is 15 dB for the corresponding minimum grazing angle

\[
\psi_m \approx \sqrt{0.05 \lambda d / (d_1 d_2)} \text{ radians}
\]

where antennas are barely intervisible. A comparison with the CCIR Atlas of smooth-earth diffraction curves shows that the attenuation relative to free space varies from 10 to 20 decibels for a zero angular distance \( \theta = 0 \), \( \psi = 0 \) except for extremely low antennas.
Figure 5.1a shows how rays will bend above an earth of actual radius $a_0 = 6370$ kilometers, while figure 5.1b shows the same rays drawn as straight lines above an earth of effective radius $a$. Antenna heights above sea level, $h_1$ and $h_2$, are usually slightly greater than the effective antenna heights $h'_1$ and $h'_2$, defined in 5.2.1. This difference arises from two circumstances: the smooth curve may be a curve-fit to the terrain instead of representing sea level, and straight rays above an effective earth overestimate the ray bending at high elevations. This latter correction is insignificant unless $d$ is large.
5.2.1 A Curve-Fit to Terrain

A smooth curve is fitted to terrain visible from both antennas. It is used to define antenna heights $h'_1$ and $h'_2$, as well as to determine a single reflection point where the angle of incidence of a ray $r_1$ is equal to the angle of reflection of a ray $r_2$ in figure 5.1. This curve is also required to obtain the deviation, $\sigma_h$, of terrain heights used in computing $R_e$ in (5.1). Experience has shown that both $h'_1$ and $h'_2$ should exceed 0.16\lambda for the following formulas to be applicable. One of the prediction methods listed in subsection 5.1 may be used where these formulas do not apply.

First, a straight line is fitted by least squares to equidistant heights $h_i(x_i)$ above sea level, and $x_1^2/(2a)$ is then subtracted to allow for the sea level curvature $1/a$ illustrated in figure 6.4. The following equation describes a straight line $h(x)$ fitted to 21 equidistant values of $h_i(x_i)$ for terrain between $x = x_0$ and $x = x_20$ kilometers from the transmitting antenna. The points $x_0$ and $x_20$ are chosen to exclude terrain adjacent to either antenna which is not visible from the other:

\[
\begin{align*}
    h(x) &= \bar{h} + m(x - \bar{x}) \\
    \bar{h} &= \frac{1}{21} \sum_{i=0}^{20} h_i, \quad \bar{x} = \frac{x_0 + x_{20}}{2}, \quad m = \frac{2 \sum_{i=0}^{20} h_i(x_i - x_0)}{77(x_{20} - x_0)}
\end{align*}
\]  

(5.15a)  

(5.15b)

Smooth modified terrain values given by

\[
y(x) = h(x) - x^2/(2a)
\]

will then define a curve of radius $a$ which is extrapolated to include all values of $x$ from $x = 0$ to $x = d$, the positions of the antennas.

The heights of the antennas above this curve are

\[
\begin{align*}
    h'_1 &= h_{ts} - h(0), \quad h'_2 = h_{rs} - h(d).
\end{align*}
\]

(5.17)

If $h'_1$ or $h'_2$ is greater than one kilometer, a correction term, $\Delta h$, defined by (6.12) and shown on figure 6.7 is used to reduce the value given by (5.17).

Where terrain is so irregular that it cannot be reasonably well approximated by a single curve, $\sigma_h$ is large and $R_e = 0$, not because the terrain is very rough, but because it is irregular. In such a situation, method 3 of section 5.1 may be useful.
5.2.2 The terrain roughness factor, $\sigma_h$

The terrain roughness factor $\sigma_h$ in (5.1) is the root-mean-square deviation of modified terrain elevations, $\gamma_i$, relative to the smooth curve defined by (5.16), within the limits of the first Fresnel zone in the horizontal reflecting plane. The outline of a first Fresnel zone ellipse is determined by the condition that

$$r_{11} + r_{21} = r_1 + r_2 + \lambda/2$$

where $r_{11} + r_{21}$ is the length of a ray path corresponding to reflection from a point on the edge of the Fresnel zone, and $r_1 + r_2$ is the length of the reflected ray for which angles of incidence and reflection are equal. Norton and Omberg [1947] give general formulas for determining a first Fresnel zone ellipse in the reflecting plane. Formulas are given in annex III for calculating distances $x_a$ and $x_b$ from the transmitter to the two points where the first Fresnel ellipse cuts the great circle plane.

A particularly interesting application of some of the smooth-earth formulas given in this section is the work of Lewin [1962] and others in the design of space-diversity configurations to overcome phase interference fading over line-of-sight paths. Diffraction theory may be used to establish an optimum antenna height for protection against long-term power fading, choosing for instance the minimum height at which the attenuation below free space is 20 db for a horizontally uniform atmosphere with the maximum positive gradient of refractivity expected to be encountered. Then the formulas of this section will determine the optimum diversity spacing required to provide for at least one path a similar 20 db protection against multipath from direct and ground-reflected components throughout the entire range of refractivity gradients expected. In general, the refractive index gradient will vary over wider ranges on over-water paths [Ikegami, 1964].
5.3 Some Effects of Cluttered Terrain

The effects of refraction, diffraction, and absorption by trees, hills, and man-made obstacles are often important, especially if a receiving installation is low or is surrounded by obstacles. Absorption of radio energy is probably the least important of these three factors except in cases where the only path for radio energy is directly through some building material or where a radio path extends for a long distance through trees.

Studies made at 3000 MHz indicate that stone buildings and groups of trees so dense that the sky cannot be seen through them should be regarded as opaque objects around which diffraction takes place [McPetrie and Ford, 1946]. At 3000 MHz the loss through a 23-centimeter thick dry brick wall was 12 db and increased to 46 db when the wall was thoroughly soaked with water. A loss of 1.5 db through a dry sash window, and 3 db through a wet one were usual values.

The only objects encountered which showed a loss of less than 10 db at 3000 MHz were thin screens of leafless branches, the trunk of a single tree at a distance exceeding 30 meters, wood-framed windows, tile or slate roofs, and the sides of light wooden huts. Field strengths obtained when a thick belt of leafless trees is between transmitter and receiver are within about 6 db of those computed assuming Fresnel diffraction over an obstacle slightly lower than the trees. Loss through a thin screen of small trees will rarely exceed 6 db if the transmitting antenna can be seen through their trunks. If sky can be seen through the trees, 15 db is the greatest expected loss.

The following empirical relationship for the rate of attenuation in woods has been given by Saxton and Lane [1955]:

\[ A_w = d(0.244 \log f - 0.442) \text{ decibels, } \quad (f > 100 \text{ MHz}) \]  (5.18)

where \( A_w \) is the absorption in decibels through \( d \) meters of trees in full leaf at a frequency \( f \) megahertz.

The situation with a high and a low antenna in which the low antenna is located a small distance from and at a lower height than a thick stand of trees is quite different from the situation in which both antennas may be located in the woods. Recent studies at approximately 500 MHz show the depression of signal strengths below smooth earth values as a function of clearing depth, defined as the distance from the lower antenna to the edge of the woods [Head, 1960]. The following empirical relation is established:

\[ \Delta_c = 52 - 12 \log d_c \text{ decibels} \]  (5.19)

where \( \Delta_c \) is the depression of the field strength level below smooth earth values and \( d_c \) is the clearing depth in meters.
5.4 Sample Calculation of Line-of-Sight Predictions

Attenuation relative to free space is predicted for a short line-of-sight path shown in figure 5.2. Measurements at a frequency of 100 MHz were made using vertical polarization. The transmitting and receiving antennas are 4 meters and 9 meters, respectively, above ground.

A straight line is fitted by least squares to the terrain visible from both antennas. Terrain near the transmitter is excluded because it is shadowed by high foreground terrain. Twenty-one equidistant points \( x_1, x_2, \ldots, x_{20} \) are chosen as shown on figure 5.2a, and the corresponding terrain heights, \( h_1, \ldots, h_{20} \), are read. From (5.15) the average terrain height \( \bar{h} \) is 1531.8 m, the average distance \( \bar{x} \) is 13.0 km, and the slope \( m \) is -6.0 meters per kilometer. The equation for the straight line is then

\[
h(x) = 1531.8 - 6(x-13) = 1531.8 - 6(x-13) \cdot 10^{-3} \text{ km.}
\]

An effective earth's radius, \( a \), is obtained using figure 4.1 and equations (4.3) and (4.4). For this area in Colorado \( N_s \) is 280 and \( a = 8200 \text{ km} \). From (5.16) the adjustment to allow for the sea level curvature is

\[
y(x) = h(x) - \frac{x}{16400} \text{ km.}
\]

Figure 5.2b shows the curve \( y(x) \) vs \( x \) and terrain which has been modified to allow for the sea level curvature.

At the transmitter, \( x = 0 \) and \( h(x = 0) = 1609.5 \text{ m} \). At the receiver, \( x = d = 19.75 \text{ km} \) and \( h(x = 19.75) = 1491.4 \text{ m} \). From (5.17) the antenna heights above the smooth reflecting plane are then:

\[
h_1' = h_1 - h(0) = 1647.1 - 1609.5 = 37.6 \text{ m} = 0.0376 \text{ km},
\]

\[
h_2' = h_2 - h(d) = 1524.0 - 1491.4 = 32.6 \text{ m} = 0.0326 \text{ km},
\]

where \( h_1 = 1647.1 \text{ m} \) and \( h_2 = 1524.0 \text{ m} \) are the heights above sea level at the transmitter and receiver respectively. At 100 MHz \( (\lambda = 3 \text{ m}) \), the criterion that both \( h_1' \) and \( h_2' \) must exceed 0.16 \( \lambda \) is met. Neither \( h_1' \) nor \( h_2' \) exceeds one kilometer, so no correction factor \( \Delta h \), is required. From (5.6) and (5.7) the distances \( d_1 \) and \( d_2 \) from each antenna to the point of specular reflection are

\[
d_1 = d(1 + h_2'/h_1')^{-1} = 10.58 \text{ km}, \quad d_2 = d(1 + h_1'/h_2')^{-1} = 9.17 \text{ km},
\]

and the grazing angle \( \psi \) is

\[
\tan \psi = h_1'/d_1 = h_2'/d_2 = 0.003554
\]

\[
\psi = 0.003554 \text{ radians.}
\]
From (5.9) the path length difference, $\Delta r$, between direct and reflected rays is

$$\Delta r = \left[ d^2 + (h'_1 + h'_2)^2 \right]^{\frac{1}{2}} - \left[ d^2 + (h_1 - h_2)^2 \right]^{\frac{1}{2}} = 1.2413 \times 10^{-4} \text{ km}.$$

The approximation

$$\Delta r \approx 2h'_1h'_2/d = 1.2413 \times 10^{-4} \text{ km} = 0.124 \text{ m} = 0.04\lambda$$

is also valid in this case. Note that $\Delta r$ is less than $0.12\lambda$ and optical methods including a divergence factor may underestimate the attenuation.

One should note that important reflections might occur from the high ground near the transmitter. In this case the reflecting plane would correspond to the foreground terrain giving $h'_1 = 4$ m, $h'_2 = 50$ m, $d_1 = 1.53$ km, $d_2 = 18.22$ km and $\Delta r = 0.02$ m which is much less than $0.16\lambda$. Optical methods would not be applicable here.

The attenuation relative to free space may be estimated using one of the methods described in subsection 5.1. Of these, methods 4 and 5 would apply in this case. Choosing heights $h'_1 = 4$ m, $h'_2 = 25$ m, as heights above foreground terrain, the theoretical smooth earth curves in the CCIR Atlas [1959] show the predicted field to be about 36 db below the free space value. The "standard" propagation curves, annex I, figure I.7, drawn for 100 MHz and $h'_1 = h'_2 = 30$ meters show the median basic transmission loss to be about 15 db below the free space loss. Greater attenuation would be expected with lower antennas over irregular terrain. Method 5 using the empirical curve through data recorded at random locations, annex I, figure I.1 shows the attenuation to be about 20 db below free space. These data were recorded with an average transmitter height of about 250 m, and a receiver height of 10 m.

For the very low antennas used on this Colorado path one would expect the losses to exceed the values shown on figures I.7 and I.1, and also to exceed the theoretical smooth earth value of $A \approx 36$ db obtained from the CCIR Atlas. Spot measurements yield a value of about 40 db.

If a prediction were desired for transmission over the same path at 300 MHz, $\lambda = 1$ m, then $\Delta r = 0.124$ m is slightly greater than $0.12\lambda$ and optical methods could be used. Using the value $\Delta r = 0.124$ m the path length difference in electrical radians $2\pi \Delta r / \lambda = 0.7805$ radians. As a check, this quantity may be computed using (5.14a):

$$2\pi \Delta r / \lambda = 41.917 f h'_1h'_2/d = 0.7805 \text{ radians} = 44.7 \text{ degrees}.$$ 

Equation (5.4) shows the attenuation relative to free space assuming a single ground reflection from the smooth curve $y(x)$, figure 5.2b. Assuming that free space gains are realized so that $G_p = 10 \log g_{01} g_{02}$ the equation may be written

5-12
\[ A = -10 \log \left[ 1 + R_e^2 - 2 R_e \cos \left( \frac{2\pi \Delta r}{\lambda} - \phi \right) \right] \]

where \( R_e \) is the effective reflection coefficient defined by (5.1):

\[ R_e = DR_r \left( \frac{g_{r1} g_{r2}}{g_{ol} g_{o2}} \right)^{\frac{1}{2}} \exp \left( -0.6 \frac{e_h \sin \psi}{\lambda} \right). \]

With \( f = 300 \) MHz, and \( \tan \psi = 0.003554 \), figure III.3, annex III shows the theoretical reflection coefficient \( R = 0.97 \) and the phase shift \( c = 0 \) for vertical polarization over average ground. The angle between the direct and the reflected ray is small so the ratio of gains in (5.1) may be considered to be unity. The divergence factor \( D \) and effective reflection coefficient \( R_e \) are

\[ D = \left( 1 + \frac{2d_1 d_2}{\lambda \tan \psi} \right)^{-\frac{1}{2}} = 0.865 \]

\[ R_e = 0.839 \exp \left( -0.6 \frac{e_h \sin \psi}{\lambda} \right). \]

The terrain roughness factor, \( e_h \), is the root-mean-square deviation of modified terrain elevations relative to the curve \( y(x) \) within the limits of the first Fresnel zone in the horizontal reflecting plane. The first Fresnel ellipse cuts the great circle plane at two points \( x_a \) and \( x_b \) kilometers from the transmitter. The distances \( x_a \) and \( x_b \) may be computed using equations (III.18) or (III.19) to (III.21) of annex III,

\[ B = 0.135, \ x_0 = 10.02, \ x_1 = 9.12 \]

\[ x_a = x_0 - x_1 = 0.90 \text{ km}, \ x_b = x_0 + x_1 = 19.14 \text{ km} \]

The first Fresnel zone cuts the great circle plane at points 0.9 and 19.14 km from the transmitter with an intervening distance of 18.24 km. Equidistant points are chosen at \( x = 1, 2, \ldots, 19 \) and corresponding modified terrain heights and values of \( y(x) \) are obtained. With height differences in kilometers:

\[ \sigma^2_h = \sum_{j=1}^{19} \frac{(y_j - h_j)^2}{19}, \ \sigma_h = 0.008222. \]

The effective reflection coefficient is then

\[ R_e = 0.839 \exp -0.01753 = 0.824 \]

5-13
which is greater than 0.5 and greater than \( \sqrt{\sin \psi} \). The predicted attenuation relative to free space \( A \) is then

\[
-10 \log \left[ 1 + \frac{R_e^2}{\lambda} - 2R_e \cos \frac{2 \pi \Delta r}{\lambda} - c \right] = -10 \log \left[ 1.6793 - 1.6484 \cos 0.7805 \right] \approx 3 \text{ db}.
\]

Due to diffraction effects over irregular terrain, the attenuation \( A \) is often observed to be much greater than the values corresponding to the ray theory calculations illustrated in this example. Ray theory is most useful to identify the location and depth of nulls in an interference pattern in the region visible to two antennas. Figure 5.3 shows an interference pattern from an aircraft at 10,000 ft., transmitting on 328.2 MHz. Measured values compared with theoretical curves based on ray theory are shown on the figure.

6. DETERMINATION OF ANGULAR DISTANCE FOR TRANSHORIZON PATHS

The angular distance, $\theta$, is the angle between radio horizon rays in the great circle plane defined by the antenna locations. This important parameter is used in diffraction theory as well as in forward scatter theory. Angular distance depends upon the terrain profile, as illustrated in figure 6.1, and upon the bending of radio rays in the atmosphere. Figure 6.1 assumes a linear dependence on height of the atmospheric refractive index, $n$, which implies a nearly constant rate of ray refraction. If heights to be considered are less than one kilometer above the earth's surface, the assumption of a constant effective earth's radius, $a$, makes an adequate allowance for ray bending. Atmospheric refractivity $N = (n - 1) \times 10^6$ more than one kilometer above the earth's surface, however, is assumed to decay exponentially with height [Bean and Thayer, 1959]. This requires corrections to the effective earth's radius formulas, as indicated in subsection 6.4.

To calculate $\theta$, one must first plot the great circle path and determine the radio horizons.

6.1 Plotting a Great Circle Path

For distances less than 70 kilometers, the great circle path can be approximated by a rhumb line, which is a line intersecting all meridians at the same angle. For greater distances, the organization of a map study is illustrated on figure 6.2. Here, a rhumb line is first plotted on an index map to show the boundaries of available detailed topographic sheets. Segments of the actual great circle path are later plotted on these detailed maps.

The spherical triangle used for the computation of points on a great circle path is shown on figure 6.3, where PAB is a spherical triangle, with A and B the antenna terminals, and P the north or south pole. B has a greater latitude than A, and P is in the same hemisphere. The triangle shown is for the northern hemisphere but may readily be inverted to apply to the southern hemisphere. B' is any point along the great circle path from A to B, and the triangle PAB' is the one actually solved. The latitudes of the points are denoted by $\phi_A$, $\phi_B$, and $\phi_{B'}$, while $C$ and $C'$ are the differences in longitude between A and B and A and B', respectively. $Z$ and $Z'$ are the corresponding great circle path lengths. The following formulas are practical for hand computations as well as for automatic digital computers. Equations (6.1) to (6.4) have been taken, in this form, from a well-known reference book [I.T. and T., 1956], where they appear on pages 730-739.

The initial bearings (X from terminal A, and Y from terminal B) are measured from true north, and are calculated as follows:

$$\tan \frac{Y - X}{2} = \cot \frac{C}{2} \left[ \left( \sin \frac{\phi_B - \phi_A}{2} \right) \left( \cos \frac{\phi_B + \phi_A}{2} \right) \right]$$  \hspace{1cm} (6.1)
\[
\tan \frac{Y + X}{2} = \cot \frac{C}{2} \left[ \left( \cos \frac{\phi_B - \phi_A}{2} \right) \Bigg/ \left( \sin \frac{\phi_B + \phi_A}{2} \right) \right] \quad (6,2)
\]

\[
\frac{Y + X}{2} + \frac{Y - X}{2} = Y, \quad \text{and} \quad \frac{Y + X}{2} - \frac{Y - X}{2} = X. \quad (6,3)
\]

The great circle distance, \( Z \), is given by

\[
\tan \frac{Z}{2} = \tan \frac{\phi_B - \phi_A}{2} \left[ \left( \sin \frac{Y + X}{2} \right) \Bigg/ \left( \sin \frac{Y - X}{2} \right) \right]. \quad (6,4)
\]

To convert the angle \( Z \) obtained in degrees from (6.4) to units of length, the following is used, based on a mean sea level earth's radius of 6370 km:

\[
d_{\text{km}} = 111.18 Z^\circ. \quad (6,5)
\]

The following formulas show how to calculate either the latitude or the longitude of a point on the great circle path, when the other coordinate is given. The given coordinates correspond to the edges of detailed maps, and to intermediate points usually about 7.5 minutes apart, so that straight lines between points will adequately approximate a great circle path.

For predominantly east-west paths, calculate the latitude \( \phi_B' \) for a given longitude difference \( C' \):

\[
\cos Y' = \sin X \sin C' \sin \phi_A - \cos X \cos C'
\]

\[
\cos \phi_B' = \sin X \cos \phi_A / \sin Y'. \quad (6,6,7)
\]

For predominantly north-south paths, calculate the longitude difference \( C' \) for a given latitude \( \phi_B' \):

\[
\sin Y' = \sin X \cos \phi_A / \cos \phi_B'
\]

\[
\cot \frac{C'}{2} = \tan \frac{Y' - X}{2} \left[ \left( \cos \frac{\phi_B' + \phi_A}{2} \right) \Bigg/ \left( \sin \frac{\phi_B' - \phi_A}{2} \right) \right]. \quad (6,9)
\]

Where the bearing of a path is close to 45 degrees, either method may be used.
6.2 Plotting a Terrain Profile and Determining the Location of Radio Horizon Obstacles

This subsection explains how to determine the sea level arc distance, \( d_{Lt,r} \), from an antenna to its radio horizon obstacle, and the height, \( h_{Lt,r} \), of this obstacle above mean sea level. The horizon obstacles are represented by the points \((d_{Lt}, h_{Lt})\) and \((d_{Lr}, h_{Lr})\) in the great circle plane containing the antennas. These points may be determined by the tops of high buildings, woods, or hills, or may be entirely determined by the bulge of the earth itself. All of the predictions of this paper replace the earth by a cylinder whose elements are perpendicular to the great circle plane and whose cross-section is in general irregular and determined by the antenna and horizon locations in the great circle plane. When the difference in elevations of antenna and horizon greatly exceeds one kilometer, ray tracing is necessary to determine the location of radio horizons accurately [Bean and Thayer, 1959].

Elevations \( h_i \) of the terrain are read from topographic maps and tabulated versus their distances \( x_i \) from the transmitting antenna. The recorded elevations should include those of successive high and low points along the path. The terrain profile is plotted on linear graph paper by modifying the terrain elevations to include the effect of the average curvature of the radio ray path and of the earth's surface. The modified elevation \( y_i \) of any point \( h_i \) at a distance \( x_i \) from the transmitter along a great circle path is its height above a plane which is horizontal at the transmitting antenna location:

\[
y_i = h_i - \frac{x_i^2}{2a}
\]

where the effective earth's radius, \( a \), in kilometers is calculated using (4.4), or is read from figure 4.2 as a function of \( N \). The surface refractivity, \( N \), is obtained from (4.3), where \( N_o \) is estimated from the map on figure 4.1.

A plot of \( y_i \) versus \( x_i \) on linear graph paper is the desired terrain profile. Figure 6.4 shows the profile for a line-of-sight path. The solid curve near the bottom of the figure indicates the shape of a surface of constant elevation \( (h = 0 \text{ km}) \). Profiles for a path with one horizon common to both antennas and for a path with two radio horizons are shown in figures 6.5 and 6.6. The vertical scales of these three figures are exaggerated in order to provide a sufficiently detailed representation of terrain irregularities. Plotting terrain elevations vertically instead of radially from the earth's center leads to negligible errors where vertical changes are small relative to distances along the profile.

On a cartesian plot of \( y_i \) versus \( x_i \), as illustrated in figures 6.4, 6.5, and 6.6, the ray from each antenna to its horizon is a straight line, provided the difference in antenna and horizon elevations is less than one kilometer. Procedures to be followed where this is not the case are indicated in the next subsection.
6.3 Calculation of Effective Antenna Heights for Transhorizon Paths

If an antenna is located on another structure, or on a steep cliff or mountainside, the height of this structure, cliff, or mountain above the surrounding terrain should be included as part of the antenna height. To obtain the effective height of the transmitting antenna, the average height above sea level \( \overline{h}_t \) of the central 80 per cent of the terrain between the transmitter and its horizon is determined. The following formula may be used to compute \( \overline{h}_t \) for 31 evenly spaced terrain elevations \( h_i \) for \( i = 0, 1, 2, \ldots, 30 \), where \( h_{t0} \) is the height above sea level of the ground below the transmitting antenna, and \( h_{t30} = h_Lt \):

\[
\overline{h}_t = \frac{1}{25} \sum_{i=3}^{27} h_i, \quad h_t = h_{ts} - \overline{h}_t \text{ for } \overline{h}_t < h_{t0};
\]

otherwise

\[
h_t = h_{ts} - h_{t0}
\]

where \( h_{ts} \) is the height of the transmitting antenna above mean sea level. The height \( h_r \) is similarly defined.

If \( h_t \) or \( h_r \) as defined above is less than one kilometer, \( h_{te} = h_t \) or \( h_{re} = h_r \).

For antennas higher than one kilometer, a correction \( \Delta h \), read from figure 6.7, is used to reduce \( h_t \) or \( h_r \) to the value \( h_{te} \) or \( h_{re} \):

\[
h_{te} = h_t - \Delta h_e(h_t, N_s), \quad h_{re} = h_r - \Delta h_e(h_r, N_s).
\]

The correction \( \Delta h \) was obtained by ray tracing methods described by Bean and Thayer [1959].

For a given effective earth's radius, the effective antenna height \( h_{te} \) corresponding to a given horizon distance \( d_{Lt} \) is smaller than the actual antenna height, \( h_t \). Over a smooth spherical earth with \( h_{te} < 1 \text{ km} \) and \( h_{re} < 1 \text{ km} \), the following approximate relationship exists between effective antenna heights and horizon distances:

\[
h_{te} = \frac{d_{Lt}^2}{2a}, \quad h_{re} = \frac{d_{Lr}^2}{2a}
\]

If the straight line distance \( r \) between antennas is substantially different from the sea level arc distance \( d \), as in communication between an earth terminal and a satellite, the effective antenna heights must satisfy the exact relation:

\[
h_{te} = a[\sec(d_{Lt}/a) - 1], \quad h_{re} = a[\sec(d_{Lr}/a) - 1]
\]

6-4
6.4 Calculation of the Angular Distance, \( \theta \)

The angular distance, \( \theta \), is the angle between horizon rays in the great circle plane, and is the minimum diffraction angle or scattering angle unless antenna beams are elevated. Calculations for cases where the antenna beams are elevated are given in annex III.

In calculating the angular distance, one first calculates the angles \( \theta_e \) and \( \theta_r \) by which horizon rays are elevated or depressed relative to the horizontal at each antenna, as shown on figure 6.1. In this report, all heights and distances are measured in kilometers, and angles are in radians unless otherwise specified. When the product \( \theta d \) is less than 2,

\[
\theta = \theta_\infty + \theta_e + \theta_r \tag{6.14}
\]

where \( a \) in (6.14) is the effective earth's radius defined in section 4. The horizon ray elevation angles \( \theta_e \) and \( \theta_r \) may be measured with surveying instruments in the field, or determined directly from a terrain profile plot such as that of figure 6.5 or 6.6, but are usually computed using the following equations:

\[
\theta_e = \frac{h_{Lt} - h_s}{d_{Lt}} - \frac{d_{Lt}}{2a}, \quad \theta_r = \frac{h_{Lr} - h_s}{d_{Lr}} - \frac{d_{Lr}}{2a} \tag{6.15}
\]

where \( h_{Lt} \), \( h_{Lr} \) are heights of horizon obstacles, and \( h_s, h_r \) are antenna elevations, all above mean sea level. As a general rule, the location \((h_{Lt}, d_{Lt})\) or \((h_{Lr}, d_{Lr})\) of a horizon obstacle is determined from the terrain profile by using (6.15) to test all possible horizon locations. The correct horizon point is the one for which the horizon elevation angle \( \theta_e \) or \( \theta_r \) is a maximum. When the trial values are negative, the maximum is the value nearest zero. For a smooth earth,

\[
\theta_{et, er} = -\sqrt{2 \frac{h}{a}} \text{ for } h < 1 \text{ km}. \tag{6.16}
\]

At the horizon location, the angular elevation of a horizon ray, \( \theta_{ot} \) or \( \theta_{or} \), is greater than the horizon elevation angle \( \theta_e \) or \( \theta_r \),

\[
\theta_{ot} = \theta_e + \frac{d_{Lt}}{a}, \quad \theta_{or} = \theta_r + \frac{d_{Lr}}{a}. \tag{6.16}
\]

If the earth is smooth, \( \theta_{ot} \) and \( \theta_{or} \) are zero, and \( \theta = D_s/a \), where

\[
D_s = d - d_{Lt} - d_{Lr}. \tag{6.17}
\]

Figure 6.8, valid only for \( \theta_{ot} + \theta_{or} = 0 \), is a graph of \( \theta \) versus \( D_s \) for various values of surface refractivity, \( N_s \).
In the general case of irregular terrain, the angles $\alpha_{oo}$ and $\beta_{oo}$ shown in figure 6.1 are calculated using the following formulas:

$$
\alpha_{oo} = \frac{d}{2a} + \theta_e + \frac{h_{ts} - h_{rs}}{d} \quad (6.18a)
$$

$$
\beta_{oo} = \frac{d}{2a} + \theta_r + \frac{h_{rs} - h_{ts}}{d} \quad (6.18b)
$$

These angles are positive for beyond-horizon paths. To allow for the effects of a non-linear refractivity gradient, $\alpha_{oo}$ and $\beta_{oo}$ are modified by corrections $\Delta\alpha_o$ and $\Delta\beta_o$ to give the angles $\alpha_o$ and $\beta_o$ whose sum is the angular distance, $\theta$, and whose ratio defines a path asymmetry factor $s$:

$$
\alpha_o = \alpha_{oo} + \Delta\alpha_o \quad (6.19a)
$$

$$
\beta_o = \beta_{oo} + \Delta\beta_o \quad (6.19b)
$$

$$
\theta = \alpha_o + \beta_o, \quad s = \alpha_o / \beta_o \quad (6.19c)
$$

The corrections $\Delta\alpha_o$ and $\Delta\beta_o$ are functions of the angles $\theta_{ot}$ and $\theta_{or}$, and of the distances $d_{st}$ and $d_{sr}$ from each horizon obstacle to the crossover of horizon rays. These distances are approximated as

$$
d_{st} = d_{oo} / \theta_{oo} \quad d_{sr} = d_{oo} / \theta_{oo} \quad (6.20)
$$

The sum of $d_{st}$ and $d_{sr}$ is the distance $D_s$ between horizon obstacles, defined by (6.17). Over a smooth earth $d_{st} = d_{sr} = D_s / 2$.

Figure 6.9, drawn for $N_s = 301$, shows $\Delta\alpha_o$ as a function of $\theta_{ot}$ and $d_{st}$. Similarly, $\Delta\beta_o$ is read from the figure as a function of $\theta_{or}$ and $d_{sr}$. For values of $N_s$ other than 301, the values as read from the figure are multiplied by $C(N_s)$:

$$
\Delta\alpha_o (N_s) = C(N_s) \Delta\alpha_o (301), \quad \Delta\beta_o (N_s) = C(N_s) \Delta\beta_o (301) \quad (6.21a)
$$

$$
C(N_s) = \{1.3 N_s^2 - 60 N_s\} \times 10^{-5} \quad (6.21b)
$$

For instance, $C(250) = 0.66$, $C(301) = 1.0$, $C(350) = 1.38$, and $C(400) = 1.84$. Figure 6.10 shows $C(N_s)$ plotted versus $N_s$. 

6-6
For small $\theta_{ot,r}$ no correction $\Delta\sigma_o$ or $\Delta\beta_o$ is required for values of $d_{st,r}$ less than 100 Km. When both $\Delta\sigma_o$ and $\Delta\beta_o$ are negligible:

$$\theta = \theta_{oo} - \sigma_{oo} + \beta_{oo}$$

which is the same as (6.14).

If $\theta_{ot}$ or $\theta_{or}$ is negative, compute

$$d_{st} = d_{st} - |a_{ot}| \quad \text{or} \quad d_{sr} = d_{sr} - |a_{or}|$$

or substitute $d_{st}'$ for $d_{st}$ or $d_{sr}'$ for $d_{sr}$, and read figure 6.9, using $\theta_{ot,r} = 0$.

If either $\theta_{ot}$ or $\theta_{or}$ is greater than 0.1 radian and less than 0.9 radian, determine $\Delta\sigma_o$ or $\Delta\beta_o$ for $\theta_{ot} = 0.1$ radian and add the additional correction term

$$N_s (9.97 - \cot \theta_{ot,r}) \left[ 1 - \exp(-0.05 d_{st,r}) \right] \times 10^{-6} \text{ radians}.$$

The bending of radio rays elevated more than 0.9 radian above the horizon and passing all the way through the atmosphere is less than 0.0004 radian, and may be neglected.

Other geometrical parameters required for the calculation of expected transmission loss are defined in the sections where they are used.

Many of the graphs in this and subsequent sections assume that $s = \sigma_o/\beta_o \leq 1$, where $\sigma_o$ and $\beta_o$ are defined by (6.19a) and (6.19b). It is therefore convenient, since the transmission loss is independent of the actual direction of transmission, to denote as the transmitting antenna whichever antenna will make $s$ less than or equal to unity. Alternatively, $s$ may be replaced by $1/s$ and the subscripts $t$ and $r$ may be interchanged in some of the formulas and graphs, as noted in later sections.
DISTANCES ARE MEASURED IN KILOMETERS ALONG A GREAT CIRCLE ARC.

\[ \theta_{bo} = \frac{D_s}{a} + \theta_{ot} + \frac{d}{a} + \theta_{et} + \theta_{er} \]

7. DIFFRACTION OVER A SINGLE ISOLATED OBSTACLE

A propagation path with a common horizon for both terminals may be considered as having a single diffracting knife edge. In some cases, reflection from terrain may be neglected as discussed in section 7.1; in other cases, ground reflections must be considered as shown in section 7.2 and appendix III. In actual situations, the common horizon may be a mountain ridge or similar obstacle, and such paths are sometimes referred to as "obstacle gain paths". [Barsis and Kirby, 1961; Dickson, Egli, Herbstreit and Wickizer, 1953; Furutsu, 1956, 1959, 1963; Kirby, Dougherty and McQuate, 1955; Rider, 1953; Uga, Aoyagi, and Nakahara, 1963]. A ridge or mountain peak may not provide an ideal knife edge. The theory of "rounded obstacles" is discussed by Bachynski [1960], Dougherty and Maloney [1964], Neugebauer and Bachynski [1960], Rice [1954], Wait [1958, 1959], and Wait and Conda [1959]. Furutsu [1963] and Millington, Hewitt, and Immirz [1962a] have recently developed tractable expressions for multiple knife-edge diffraction. In some cases, over relatively smooth terrain or over the sea, the common horizon may be the bulge of the earth rather than an isolated ridge. This situation is discussed in section 8.

7.1 Single Knife Edge, No Ground Reflections

A single diffracting knife edge where reflections from terrain may be neglected is illustrated in figure 7.1, where the wedge represents the knife edge. The diffraction loss \( A(v, 0) \) is shown on figure 7.1 as a function of the parameter \( v \), from Schelleng, Burrows, and Ferrell [1933] and is defined as

\[
v = \pm 2 \sqrt{\frac{\Delta r}{\lambda}} = \pm \sqrt{\frac{2d \tan \alpha \tan \beta}{\lambda}}\frac{\lambda}{\sqrt{\lambda}}
\]

(7.1a)

or in terms of frequency in MHz:

\[
v = \pm 2.583 \theta \sqrt{\frac{d_1 d_2}{d}}
\]

(7.1b)

where the distances are all in kilometers and the angles in radians. The distance

\[
\Delta r = r_1 + r_2 - r_0 = \theta \frac{d_1 d_2}{2d}
\]

is discussed in section 5, and the distances \( d_1 \) and \( d_2 \) from the knife edge to the transmitter and receiver, respectively, are shown on figure 7.1. The radio wavelength, \( \lambda \), is in the same units as the total path distance, \( d \). The angles \( \alpha_0 \), \( \beta_0 \), and \( \theta \) are defined in section 6. In this case, \( \theta = \theta \), and since \( d = d_1 = 0 \), no corrections \( \Delta \alpha_0 \) or \( \Delta \beta_0 \) are required. For the line-of-sight situation, shown in figure 7.1 and discussed in section 5.1, the angles \( \alpha_0 \) and \( \beta_0 \) are both negative, and the parameter \( v \) is negative. For transhorizon paths, \( \alpha_0 \) and \( \beta_0 \) are both positive and \( v \) is positive.
If $v$ is greater than 3, $A(v, 0)$ may be expressed by:

$$A(v, 0) = 12.953 + 20 \log v \text{ db} \quad (7.2)$$

The basic transmission loss, $L_{bd}$, for a knife-edge diffraction path is given by adding $A(v, 0)$ to the free space loss:

$$L_{bd} = L_{bf} + A(v, 0) \text{ db} \quad (7.3)$$

where $L_{bf}$ is given by (2.16). For frequencies above about 1 GHz, an estimate of the loss due to absorption (3.1) should be added to (7.3) and (7.4).

If the angles $\alpha$ and $\beta$ are small, the basic transmission loss over a knife-edge diffraction path may be written as:

$$L_{bd} = 30 \log d + 30 \log f + 10 \log \alpha + 10 \log \beta + 53.644 \text{ db} \quad (7.4)$$

which, however, is accurate only if $v > 3$, $d >> \lambda$, and $(d/\lambda) \tan \alpha \tan \beta > 4$.

For many paths, the diffraction loss is greater than the theoretical loss shown in (7.2), (7.3), and (7.4), because the obstacle is not a true knife edge, and because of other possible terrain effects. For a number of paths studied, the additional loss ranged from 10 to 20 db.

The problem of multiple knife-edge diffraction is not discussed here, but for the double knife-edge case, where diffraction occurs over two ridges, a simple technique may be used. The path is considered as though it were two simple knife-edge paths, (a) transmitter - first ridge - second ridge, and (b) first ridge - second ridge - receiver. The diffraction attenuation $A(v, 0)$ is computed for each of these paths, and the results added to obtain the diffraction attenuation over the whole path. When the parameter $v$ is positive and rather small for both parts of the path, this method gives excellent results. Methods for approximating theoretical values of multiple knife-edge diffraction have been developed by Wilkerson [1964].
7.2 Single Knife Edge with Ground Reflections

Theoretically, received fields may be increased by as much as 12 db due to enhancement, or deep nulls may occur due to cancellation of the signal by ground reflections. Reflection may occur on either or both sides of the diffracting edge. When the reflecting surface between the diffracting knife-edge and either or both antennas is more than the depth of a first Fresnel zone below the radio ray, and where geometric optics is applicable, the four ray knife-edge theory described in annex III may be used to compute diffraction attenuation. This method is used when details of terrain are known so that reflecting planes may be determined rather accurately. Using the four ray theory, the received field may include three reflected components, with associated reflection coefficients and ray path differences, in addition to the direct ray component.

When an isolated knife edge forms a common horizon for the transmitter and receiver, the diffraction loss may be estimated as:

\[ A = A(v, 0) - G(h_1) - G(h_2) \text{ db} \] (7.5)

where

\[ h_1 = 2.2325 B^2(K, b^*) \left( \frac{f^2}{a_1} \right)^{\frac{3}{2}} \text{ h_{te}} \approx 5.74 \left( \frac{f^2}{a_1} \right)^{\frac{3}{2}} \text{ h_{te}} \] (7.6a)

\[ h_2 = 2.2325 B^2(K, b^*) \left( \frac{f^2}{a_2} \right)^{\frac{3}{2}} \text{ h_{re}} \approx 5.74 \left( \frac{f^2}{a_2} \right)^{\frac{3}{2}} \text{ h_{re}} \] (7.6b)

The parameters \( b^*, K, \) and \( B(K, b^*) \) are defined in subsection 8.1. The knife-edge attenuation \( A(v, 0) \) is shown on figure 7.1, and the function \( G(h) \) introduced by Norton, Rice and Vogler [1955] is shown on figure 7.2. Effective antenna heights \( h_{te}, h_{re} \), and the distances \( d_{Lt}, d_{Lr} \) are defined in section 6. In these and other formulas, \( f \) is the radio frequency in MHz.

The function \( G(h_1, 2) \) represents the effects of reflection between the obstacle and the transmitter or receiver, respectively. These terms should be used when more than half of the terrain between an antenna and its horizon cuts a first Fresnel zone ellipse which has the antenna and its horizon as focii and lies in the great circle plane. Definite criteria are not available, but in general, if terrain near the middle distance between a transmitting antenna and its horizon is closer to the ray than \( 0.5(\lambda d_{Lt})^{\frac{1}{2}} \) kilometers, \( G(h_1) \) should be used. The same criterion, depending on \( d_{Lr} \), determines when \( G(h_2) \) should be used. When details of terrain are not known, an allowance for terrain effects, \( G(h_{1, 2}) \), should be used if \( 0.5(\lambda d_{Lt, Lr})^{\frac{1}{2}} > \left| h_{Ll, Lr} - h_{ts, rs} \right| / 2 \), where all distances and heights are in kilometers.
7.3 Isolated Rounded Obstacle, No Ground Reflections

Dougherty and Maloney [1964] describe the diffraction attenuation relative to free space for an isolated, perfectly conducting, rounded knife edge. The rounded obstacle is considered to be isolated from the surrounding terrain when

\[ k \frac{h^{2/(kr)}}{2} > 1 \]

where \( k = \frac{2\pi}{\lambda} \), \( r \) is the radius of curvature of the rounded obstacle, and \( h \) is the smaller of the two values \( \left[ (d_{L_1}^2 + r^2)^{1/2} - r \right] \) and \( \left[ (d_{L_2}^2 + r^2)^{1/2} - r \right] \).

The diffraction loss for an isolated rounded obstacle and irregular terrain shown in figure 7.3 is defined as:

\[ A(v, \rho) = A(v, 0) + A(0, \rho) + U(\rho) \text{ db} \]  

(7.7)

where \( v \) is the usual dimensionless parameter defined by (7.1) and \( \rho \) is a dimensionless index of curvature for the crest radius, \( r \) in kilometers, of the rounded knife edge:

\[ \rho = \frac{0.676 r^{3/6}}{[d/(r_1 r_2)]^{1/2}} \]  

(7.9)

where, \( f \) is the radio frequency in MHz, \( d \) is the path distance in kilometers, and \( r_1, r_2 \) shown in figure 7.3 are the distances in kilometers from the transmitter and receiver, respectively to the rounded obstacle. For all practical applications, \( r_1 r_2 \) may be replaced by \( d_1 d_2 \). Where the rounded obstacle is the broad crest of a hill, the radius of curvature, \( r \), for a symmetrical path is:

\[ r = \frac{D}{\theta} \]  

(7.10)

where \( D = d - d_{L_1} - d_{L_2} \) is the distance between transmitter and receiver horizons in kilometers, and \( \theta \) is the angular distance in radians (6.19). Where the ratio \( \alpha_o/\beta_o = 1 \), the radius of curvature is defined in terms of the harmonic mean of radii \( a_t \) and \( a_r \) defined in the next section, (8.9), and shown in figure 8.7:

\[ r = \frac{2 D_s d_{st} d_{sr}}{\theta \left( d_{st}^2 + d_{sr}^2 \right)} \]  

(7.11)

In (7.7), the term \( A(v, 0) \) is the diffraction loss for the ideal knife edge \( (r = 0) \), and is read from figure 7.1. The term \( A(0, \rho) \) is the magnitude of the intercept values \( (v = 0) \) for various values of \( \rho \) and is shown on figure 7.4. The last term \( U(\rho) \) is a function of the product \( \varphi \rho \), and is shown on figure 7.5.
Arbitrary mathematical expressions, given in annex III, have been fitted to the curves of figures 7.1, 7.3, 7.4, and 7.5 for use in programming the method for a digital computer.

The diffraction loss $A(v, \rho)$ as given by (7.7) is applicable for either horizontally or vertically polarized radio waves over irregular terrain provided that the following conditions are met:

(a) the distances $d, d_1, d_2,$ and $r$ are much larger than $\lambda,$
(b) the extent of the obstacle transverse to the path is at least as great as the width of a first Fresnel zone:
\[
\sqrt{\frac{\lambda d_1,2}{1 - \frac{d_1,2}{r/d}}},
\]
(c) the components $\alpha_0$ and $\beta_0$ of the angle $\theta$ are less than 0.175 radians, and
(d) the radius of curvature is large enough so that $(\pi r/\lambda)^{1/2} \gg 1.$

In applying this method to computation of diffraction loss over irregular terrain, some variance of observed from predicted values is to be expected. One important source of error is in estimating the radius of curvature of the rounded obstacle, because the crests of hills or ridges are rarely smooth. Differences between theoretical and observed values are apt to be greater at UHF than at VHF.
7.4 Isolated Rounded Obstacle with Ground Reflections

If a rounded obstacle has a small radius and is far from the antennas, \((7.7)\) may neglect important effects of diffraction or reflection by terrain features between each antenna and its horizon.

Such terrain foreground effects may be allowed for, on the average, by adding a term, \(10 \exp(-2.3\rho)\) to \((7.7)\). The effect of this term ranges from 10 db for \(\rho = 0\) to 1 db for \(\rho = 1\). When some information is available about foreground terrain, the \(G(h_{1,2})\) terms discussed in section 7.2 may be used if more than half of the terrain between an antenna and its horizon cuts a first Fresnel zone in the great circle plane:

\[
A = A(v, \rho) - G(h_1) - G(h_2) \quad \text{db} \tag{7.12}
\]

where \(A(v, \rho)\) is defined by \((7.7)\), \(h_1, h_2\) by \((7.6)\), and the functions \(G(h_{1,2})\) are shown on figure 7.2.

When details of terrain are known, and the reflecting surfaces between the rounded obstacle and either or both antennas are more than the depth of a first Fresnel zone below the radio ray, the geometric optics four-ray theory described in annex III may be applicable. In this case, the phase lag of the diffracted field with reference to the free space field must be considered in addition to the ray path differences of the reflected components. The phase lag \(\Phi(v, \rho)\) of the diffracted field is defined as

\[
\Phi(v, \rho) = 90v^2 + \Phi(v, 0) + \Phi(0, \rho) + \Phi(v \rho) \quad \text{degrees} \tag{7.13a}
\]

where the functions \(\Phi(v, 0), \Phi(0, \rho), \text{ and } \Phi(v \rho)\) are shown on figures 7.1, 7.4, and 7.5, respectively. For an ideal knife-edge, \(\rho = 0\), the phase lag of the diffracted field is

\[
\Phi(v, 0) = 90v^2 + \Phi(v, 0) \quad \text{for } v > 0 \tag{7.13b}
\]

and

\[
\Phi(v, 0) = \Phi(v, 0) \quad \text{for } v \leq 0 \tag{7.13c}
\]
7.5 An Example of Transmission Loss Prediction for a Rounded Isolated Obstacle

The path selected to provide an example of knife-edge diffraction calculations is located in eastern Colorado, extending from a location near Beulah, southwest of Pueblo, to Table Mesa north of Boulder. The common horizon is formed by Pikes Peak, with an elevation 4300 meters above mean sea level. For the purpose of these calculations Pikes Peak is considered to be a single rounded knife edge. The complete path profile is shown in figure 7.6. Table 7.1 gives all applicable path and equipment parameters and permits a comparison of calculated and actually measured values.

Calculations are given for single-ray diffraction, neglecting possible specular reflections from foreground terrain.

The minimum monthly surface refractivity $N_0$ (referred to mean sea level) from figure 4.1 is 300 N-units. From Table 7.1 the terminal elevations are 1905 and 1666 m, respectively. Corresponding surface refractivity values $N_s$ are 245 and 251 N-units (4.3), and the average of these values is $N_s = 248$. In this example, $N_s$ is calculated for the terminals, as the antennas are more than 150 m below their 4300 m radio horizon. Using (4.4) or an extrapolation of figure 4.2, the effective earth radius $a$ for $N_s = 248$ is found to be 7830 km.
The angular distance \( \theta \) in radians and related parameters are calculated using (6.15) and (6.18a,b): 
\[
\theta_{et} = 0.008581, \quad \theta_{er} = 0.025953, \quad \omega_{oo} = 0.021627, \quad \beta_{oo} = 0.041225.
\]
In this example, \( d_{st} \) and \( d_{sr} \) are negligibly small, and the corrections \( \Delta \omega_{oo} \) and \( \Delta \beta_{oo} \) (6.19a,b) can be neglected. Thus, \( \omega_{oo} \), \( \omega_{oo}' \), \( \beta_{oo}' \), and \( \theta = 0.063052 \) radians.

The free-space loss and the attenuation relative to free space are computed considering Pikes Peak to be a single isolated rounded obstacle. From a study of large-scale topographic maps, the distance \( D_s \) between the radio horizons at the top of the peak is estimated to be 0.040 km. With
\[
f = 751 \text{ MHz}, \quad d_1 = 146.0 \text{ km}, \quad \text{and} \quad d_2 = 77.3 \text{ km},
\]
we determine:
\[
v = 31.73 \quad (v \text{ is positive, as both } \omega_{oo} \text{ and } \beta_{oo} \text{ are greater than zero}) \quad (7.1b)
\]
\[
r = 0.6344 \quad (7.10), \quad v\rho = 0.858 \quad (7.8) \quad \text{and} \quad \rho = 0.0271
\]

The test described in section 7.3 shows that the assumption of an isolated obstacle is applicable. The components of basic transmission loss are then determined as follows:

Free-space Loss 
\[
L_{bf} = 137.0 \text{ db} \quad (2.16)
\]
\[
A(v, 0) = 43.0 \text{ db} \quad \text{figure 7.1}
\]
\[
A(0, \rho) = 6.0 \text{ db} \quad \text{figure 7.4}
\]
\[
U(v, \rho) = 5.1 \text{ db} \quad \text{figure 7.5}
\]

Totals are: \( A(v, \rho) = 54.1 \text{ db} \), and from (7.3), 
\[
L_{bd} = L_{bf} + A(v, \rho) = 191.1 \text{ db}.
\]
The average atmospheric absorption term, \( A_{ah} \), from figure 3.6 is 0.7 db. Then the total basic transmission loss value \( L_{dr} \) = 191.8 db, which is equal to the long-term reference value \( L_{cr} \). This reference value is strictly applicable only to those hours of the year which are characterized by a surface refractivity of approximately 250 N-units.

The expected behavior of the hourly median basic transmission loss for all hours of the year over this path can be determined using the methods described in section 10. A function \( V(0.5, \rho) \) which is used with \( L_{cr} \) to compute the long-term median transmission loss for a given climatic region is described in subsection 10.4. A function \( Y(q, \rho) \) describes the variability relative to this long-term median that is expected for a fraction of hours \( q \). The total cumulative distribution for this path in a Continental Temperate climate is computed as shown in subsection 10.5.

Since this is a knife-edge diffraction path, it will be necessary to calculate cumulative distributions \( Y(q, \rho) \) separately for portions of the path on each side of Pikes Peak and to combine the results as described in subsection 10.8. Effective antenna heights are computed as heights above curves fitted to terrain on each side of Pike's Peak using (5.15) and (5.16). The curves are extrapolated to each antenna and to Pike's Peak. The effective heights are then the heights of the antennas and of the Peak above these curves. From Beulah to Pikes...
Peak the terrain near the Peak is excluded because it is partially shadowed. Twenty-one evenly spaced points, \( x_i \), from \( d = 3.3 \) km to \( d = 70 \) km were selected and the corresponding terrain heights \( x_i \) were read. From (5.15b) \( \bar{h} = 2100 \) m, \( \bar{x} = 36.6 \) km, and \( m = 25.5 \), and the straight line fitted to terrain is

\[
h(x) = 2100 + 25.5(x - 36.6) \text{ meters.}
\]

At the Beulah antenna, \( x = 0 \) and \( h(x) = 1167 \) meters, at Pikes Peak \( x = 75.5 \) kilometers and \( h(x) = 3095 \) meters. The effective antenna heights are then 738 and 1205 meters (5.17). Using (10.1) to (10.3) the distances \( d_L = 262.5 \) km, \( d_s = 33.2 \) km, and the effective distance \( d_e = 34.0 \) km.

Similarly on the Table Mesa side much of the terrain is shadowed by the small peak at about 122 km and by the elevated area at about 202 km. The curve fit is therefore computed for the intervening terrain with \( x_0 = 122.5 \) km and \( x_20 = 200.5 \) km. Using 21 equidistant terrain heights between these points (5.15b) gives \( \bar{h} = 2025 \) m, \( \bar{x} = 161.5 \) km, and \( m = -9.3 \). From (5.15a) \( h(x = 75.5) = 2827, h(x = 223.3) = 1448 \) meters. The effective antenna heights are then 1473 and 218 meters (5.17), \( d_L = 222.5 \), \( d_s = 33.2 \) km, and the effective distance \( d_e = 74.3 \) km.

We thus have two paths in tandem where the effective distances are 34.0 and 74.3 km respectively. Cumulative distributions are obtained using figures 10.13, 10.14, 10.15, and equations (10.4) to (10.7). The frequency factors are \( g(0.1, f) = 1.33, g(0.9, f) = 1.29 \).

The cumulative distribution of predicted basic transmission loss for the entire path was obtained by convoluting the distributions for each part of the path, as described in sub-section 10.8. This cumulative distribution is shown graphically in figure 7.7 together with a distribution derived from measurements over this path, reflecting 1056 hours of data obtained in 1960 and 1962.

The confidence limits on figure 7.7 were derived assuming that:

$$\sigma^2_c(q) = 16.73 + 0.12 \chi^2(q)$$

where the variance $\sigma^2_c(0.5) = 12.73 \text{ dB}^2$ given in (V.40) has been increased by 4 dB$^2$ to allow for equipment and reading errors.

8. DIFFRACTION OVER SMOOTH EARTH AND OVER IRREGULAR TERRAIN

Diffraction attenuation over an isolated ridge or hill has been discussed in section 7. The following methods are used to compute attenuation over the bulge of the earth and over irregular terrain. The methods are applicable to the far diffraction region, where the diffracted field intensity may be determined by the first term of the Van der Pol-Bremmer residue series [Bremmer, 1949]. This region extends from near the radio horizon to well beyond the horizon. A criterion is given to determine the minimum distance for which the method may be used. In some situations the first term of the series provides a valid approximation to the diffracted field even at points slightly within line-of-sight [Vogler, 1964].

A simplified graphical method for determining ground wave attenuation over a spherical homogeneous earth in this far diffraction region was recently developed by Vogler [1964], based on a paper by Norton [1941]. The method described in section 8.1 is applicable to either horizontal or vertical polarization, and takes account of the effective earth's radius, ground constants, and radio frequency. In section 8.2, a modification of the method for computing diffraction attenuation over irregular terrain is described, and section 8.3 considers the special case of a common horizon which is not an isolated obstacle.

For frequencies above 1000 MHz, the attenuation due to gaseous absorption should be added to the diffraction loss. See (3.1) and figure 3.6.

8.1 Diffraction Attenuation Over a Smooth Earth

The attenuation relative to free space may be expressed in terms of a distance dependence, the dependence on antenna heights, and the dependence on electromagnetic ground constants, the earth's radius, and the radio frequency:

\[ A = C(x_0) - F(x_1) - F(x_2) - C_1(K, b^*) + A_a \]  

(8.1)

where \( A_a \) is the atmospheric absorption, given by (3.5), and

\[ x_0 = d B_o', \quad x_1 = d_{Lt} B_o', \quad x_2 = d_{Lr} B_o \]  

(8.1a)

\[ B_o = \frac{1}{3} C_o^2 B(K, b^*), \quad C_o = (8497/a)^{1/3} \]  

(8.1b)

The basic diffraction transmission loss \( L_{bd} \) is:

\[ L_{bd} = L_{bf} + A_{db}, \]  

(8.2)

where the basic transmission loss in free space, \( L_{bf} \), is given by (2.16).

The distances \( d, d_{Lt}, d_{Lr} \), and the effective earth's radius, \( a \), have been defined in sections 4 and 6, and \( f \) is the radio frequency in megahertz.
The parameters $K$ and $b^\circ$ depend on polarization of the radio wave and the relative dielectric constant, $\epsilon$, and conductivity, $\sigma$, of the ground. Figures 8.1 and 8.2 show curves of $K$ and $b^\circ$ versus frequency for combinations of $\epsilon$ and $\sigma$ corresponding to poor, average, and good ground, and to sea water. Figure 8.1 shows $K$ for $a = 8497$ km. For other values of effective earth's radius,

$$K(a) = C_0 K(8497).$$

(8.3)

General formulas for $K$ and $b^\circ$ for both horizontal and vertical polarization are given in section III.4 of annex III.

The parameter $B(K, b^\circ)$ in (8.2b) is shown as a function of $K$ and $b^\circ$ in figure 8.3. The limiting value $B = 1.607$ for $K \to 0$ may be used for most cases of horizontal polarization. The parameter $C_4(K, b^\circ)$ in (8.1) is shown in figure 8.4.

The function $G(x_0)$ in (8.1) is shown on figures 8.5 and 8.6, and is defined as

$$G(x_0) = 0.05751 x_0 - 10 \log x_0$$

(8.4)

and the height functions $F(x_{1,2})$ are plotted in figures 8.5 and 8.6 versus $K$ and $b^\circ$.

For large values of $x_1$ or $x_2$, $F(x)$ is approximately equal to $G(x)$.

Because this method is based on only the first term of the residue series, it is limited to the following distances to insure that $A$ is accurate within approximately 1.5 db:

$$x_0 - x_1(\Delta x_1) - x_2(\Delta x_2) > 335, \quad \text{for } B = 1.607, \quad (K \leq 0.1) \quad (8.5a)$$

$$x_0 - x_1(\Delta x_1) - x_2(\Delta x_2) > 115, \quad \text{for } B = 0.700, \quad (K \geq 10). \quad (8.5b)$$

For values of $B$ lying between these two limits, linear interpolation between the $\Delta(x)$ curves of figure 8.6, and the two minimum values in (8.5) gives a fair approximation of the range of validity of (8.1). Using linear interpolation:

$$x_0 - x_1 \Delta(x_1, B) - x_2 \Delta(x_2, B) > x_{\min}$$

(8.6)

where

$$x_{\min} = 335 - 242.6 (1.607 - B) \quad (8.7a)$$

$$\Delta(x, B) = \Delta(x, 1.607) + 1.103(1.607 - B) [\Delta(x, 0.700) - \Delta(x, 1.607)] \quad (8.7b)$$

$\Delta(x, 0.700)$ and $\Delta(x, 1.607)$ are the values read from the upper and lower curves of $\Delta x$ in figure 8.6.
8.2 Diffraction Over Irregular Terrain

To compute diffraction attenuation over irregular terrain, the single effective earth's radius, \( a \), used in (8.2) is replaced by four different radii as shown in figure 8.7. The radii \( a_1 \) and \( a_2 \) of the terrain between the antennas and their horizons, and the radii \( a_t \) and \( a_r \) of the terrain between radio horizons and the crossover point of horizon rays are defined by

\[
a_1 = \frac{d_{Lt}}{2h_{te}}, \quad a_2 = \frac{d_{Lr}}{2h_{re}}
\]

\[
a_t = \frac{D_{st}}{\theta d_{st}}, \quad a_r = \frac{D_{sr}}{\theta d_{sr}}.
\]

The distances \( D_{st}, d_{st}, d_{sr}, d_{Lt}, d_{Lr} \), the effective antenna heights \( h_{te} \) and \( h_{re} \), and the angular distance \( \theta \) are defined in section 6.

These four radii are used in (8.2) and (8.3) to obtain values of \( K(a) = K_{1,2, t, r} \) for each of the four radii. Corresponding values \( B_{1,2,t,r} \) are then read from figure 8.3 for each value of \( K \).

The diffraction attenuation relative to free space is then:

\[
A = G(x_0) - F(x_1) - F(x_2) - C_1(K_{1,2}) + A_a
\]

where \( A_a \) is the atmospheric absorption defined by (3.1), and is negligible for frequencies less than 1 GHz, and \( C_1(K_{1,2}) \) is the weighted average of \( C_1(K_1, b) \) and \( C_1(K_2, b) \) read from figure 8.4:

\[
C_1(K_{1,2}) = \frac{x_1 C_1(K_1) + x_2 C_1(K_2)}{x_1 + x_2}
\]

\[
x_1 = \frac{B_{o1}}{B_{01}} d_{Lt}, \quad x_2 = \frac{B_{o2}}{B_{02}} d_{Lr}
\]

\[
x_0 = \frac{B_{ot}}{B_{0t}} d_{st} + \frac{B_{or}}{B_{0r}} d_{sr} + x_1 + x_2
\]

\[
B_{o1} = \frac{f^2}{2} C_{o1} B_{1t}, \quad B_{o2} = \frac{f^2}{2} C_{o2} B_{2t},
\]

\[
B_{ot} = \frac{f^2}{2} C_{ot} B_{1r}, \quad B_{or} = \frac{f^2}{2} C_{or} B_{2r}.
\]

This method is applicable to computation of diffraction attenuation over irregular terrain for both vertical and horizontal polarization for transhorizon paths. The method may be somewhat simplified for two special cases: diffraction over paths where \( d_{st} = d_{sr} \), and for most paths when horizontal polarization is used.
8.2.1 Diffraction over paths where \( d_{st} = d_{sr} \)

For paths where the distances \( d_{st} \) and \( d_{sr} \) are equal, the parameter \( x_0 \) may be defined in terms of \( D_s \) and the corresponding earth's radius \( a_s \):

\[
x_0 = B_{os} D_s + x_1 + x_2 \quad (8.14)
\]

\[
D_s = 2 d_{st} = 2 d_{sr}, \quad a_s = D_s / 8, \quad C_{os} = (8497 / a_s)^{1/3}, \quad B_s = B(K_s, b^*) \quad (8.15a)
\]

\[
B_{os} = \frac{1}{3} C_{os}^2 B_s \quad (8.15b)
\]

where \( x_1 \) and \( x_2 \) are defined by (8.12). The diffraction attenuation is then computed using (8.10).

8.2.2 For horizontal polarization

For horizontally polarized radio waves, at frequencies above 100 MHz, and with \( K(a) \leq 0.001 \), the parameter \( B(K, b) \) approaches a constant value, \( B \approx 1.607 \), and \( C_1(K, b) = 20.03 \) dB. Assuming \( B = 1.607 \) and \( C_1 = 20.03 \), the diffraction attenuation may be computed as follows:

\[
A = G(x_0) - F(x_1) - F(x_2) - 20.03 \text{ db} \quad (8.16a)
\]

\[
x_1 = 669 f^{1/3} d_{Lt} / a_1^{2/3}, \quad x_2 = 669 f^{1/3} d_{lr} / a_2^{2/3} \quad (8.16b)
\]

\[
x_0 = 669 f^{1/3} g_3^{3/2} D_{st} + x_1 + x_2 \quad (8.16c)
\]

where

\[
D_{st} = (d_{st} d_{sr})^{1/2} \left( \frac{d_{st}^{1/3} + d_{sr}^{1/3}}{(d_{st} + d_{sr})^{1/3}} \right).
\]

The parameter \( D_{st} \) is shown in figure 8.8 as a function of \( d_{st} \) and \( d_{sr} \).

For paths where \( d_{st} = d_{sr} \), using horizontal polarization, the parameter \( x_0 \) simplifies to

\[
x_0 = 669 f^{1/3} (g_3 D_s^{1/3} + x_1 + x_2). \quad (8.16d)
\]
8.3 Single-Horizon Paths, Obstacle not Isolated

In some cases, over rather regular terrain or over the sea, a common horizon may be the bulge of the earth rather than an isolated ridge or mountain. For such paths, the path distance, $d$, is just the sum of $d_{Lt}$ and $d_{Lr}$, and in this case, the method described in section 8.2 is simplified to one with only two earth's radii instead of four. The parameters $x_1$ and $x_2$ are defined by (8.12), and $x_0 = x_1 + x_2$. The diffraction attenuation is then computed using (8.10).

The diffraction loss predicted by this method agrees very well with observed values over a number of paths in the United Kingdom and the United States where the common horizon is not isolated.

For transhorizon paths of short to medium length, when it is not known whether diffraction or scatter is the dominant propagation mechanism, both diffraction and scatter loss should be computed. The next section shows how to compute scatter loss, and how to combine the two computed values when they are nearly equal.

9. FORWARD SCATTER

This section gives methods for calculating reference values of long-term median radio transmission loss over paths that extend well beyond the horizon and for combining diffraction and scatter transmission loss estimates where this is appropriate. Empirical estimates of the median values and long-term variability of transmission loss for several climatic regions and periods of time are given in section 10 and annex III.

For long tropospheric paths the propagation mechanism is usually forward scatter, especially during times of day and seasons of the year when ducts and elevated layers are rare. Often, for other periods of time, as scattering becomes more coherent it is more properly called reflection. The examination of transmission loss variation over a particular path during some period for which detailed information about layer heights, tilts, and intensities is available can be very illuminating; see for instance Josephson and Eklund [1958]. Sometimes no distinction can be made between "forward scatter" from a turbulent atmosphere and "incoherent reflections" from patchy elevated layers. The first viewpoint is developed in papers by Pekeris [1947], Booker and Gordon [1950a], Megaw [1950, 1954, 1957], Millington [1958], Staras [1952, 1955], Tao [1957], Troitski [1956, 1957a], Villars and Weisskopf [1955], Voge [1953, 1955], and Wheelon [1957, 1959], while the second viewpoint is emphasized in papers by Beckmann [1957, 1960, 1961a, b], du Castel, Misme, and Voge [1958], Friis, Crawford and Hogg [1957], Starkey, Turner, Badcoe, and Kitchen [1958], and Voge [1956, 1960]. The general prediction methods described here are for the most part consistent with either viewpoint, and agree with long-term median values for all available data. A brief discussion of forward scatter theories is given in annex IV.

The reference value, \( L_{bsr} \), of long-term median basic transmission loss due to forward scatter is

\[
L_{bsr} = 30 \log f - 20 \log d + F(\theta d) - F_o + H_o + A_a \text{ db} \tag{9.1}
\]

For most applications the first three terms of (9.1) are sufficient for calculating \( L_{bsr} \). In (9.1) \( f \) is the radio frequency in MHz, and \( d \) is the mean sea level arc distance in kilometers. The attenuation function \( F(\theta d) \), the scattering efficiency term \( F_o \), and the frequency gain function \( H_o \), are discussed in the following subsections. Atmospheric absorption, \( A_a \), defined by (3.1) and shown on figure 3.6, may be neglected at lower frequencies, but may be more than 2 db over a long path at 1000 MHz, and becomes increasingly important with increasing frequency.

For ground-based scatter links the sea level arc distance, \( d \), and the straight line distance, \( r_o \), between antennas are approximately equal. To estimate transmission loss between the earth and a satellite, where \( r_o \) is much greater than \( d \), a term 20 log(\( r_o / d \))
should be added to the reference value $L_{bsr}$. Annex III contains a discussion of transmission loss expected when antenna beams are elevated above the horizon, or directed away from the great circle plane determined by the antenna locations.

The median forward scatter transmission loss, $L_{bsr}$, is the basic transmission loss, $L_{bsr}$, minus the path antenna gain, $G_p$. Section 9.4 shows how to estimate the loss in path antenna gain, $L_{gp}$, when there is a loss in antenna gain due to scatter. Section 9.5 shows how to combine diffraction and scatter losses. Following Arons [1956], the scattering of diffracted fields and the diffraction of scatter fields are ignored.

9.1 The Attenuation Function $F(\theta d)$

The attenuation function $F(\theta d)$ depends upon the most important features of the propagation path and upon the surface refractivity, $N_s$. The function includes a small empirical adjustment to data available in the frequency range from 100 to 1000 MHz.

For most land-based scatter links figure 9.1 may be used, where $F(\theta d)$ is plotted versus the product $\theta d$ for $N_s = 400, 350, 301$ and $250$. The path distance, $d$, is in kilometers and the angular distance, $\theta$, in radians. For values of $\theta d \leq 10$ the curves of figure 9.1 are valid for all values of the asymmetry parameter $s = a_o / \beta_o$. For values of $\theta d$ greater than 10 the curves may be used for values of $s$ from 0.7 to unity. For $s$ greater than 1 use $1/s$ in reading the graph.

For highly asymmetrical paths with $\theta d > 10$, figures III.11 to III.14 of annex III are used to obtain $F(\theta d)$. Annex III also contains analytical functions fitted to the curves $F(\theta d)$ for $0.7 \leq s \leq 1$ for all values of the product $\theta d$ for $N_s = 301$. A function is also given to adjust these computed values for all values of $N_s$. Using the analytic functions for $F(\theta d)$ with $N_s = 301$, the reference median basic transmission loss is

For $\theta d \leq 10$:

$$L_{bsr} \approx 135.8 + 30 \log f + 30 \log \theta + 10 \log d + 0.332 \theta d$$  \hspace{1cm} (9.2a)$$

For $10 < \theta d \leq 50$:

$$L_{bsr} \approx 129.5 + 30 \log f + 37.5 \log \theta + 17.5 \log d + 0.212 \theta d$$  \hspace{1cm} (9.2b)$$

Reference values may be computed in a similar manner for other values of $N_s$.

The approximations in (9.2) do not make any allowance for the frequency gain function, $H_f$. For usual cases of transmission at frequencies above 400 MHz the approximations in (9.2) give good results. For the higher frequencies an estimate of atmospheric absorption should be added. For lower frequencies, or lower antenna heights, ground-reflected energy tends to cancel the direct ray and the approximation in (9.2) will underestimate the transmission loss.
9.2 The Frequency Gain Function, $H_0$

It is assumed that if antennas are sufficiently high, reflection of energy by the ground doubles the power incident on scatterers visible to both antennas, and again doubles the power scattered to the receiver. As the frequency is reduced, effective antenna heights $h_{te}/\lambda$ and $h_{re}/\lambda$ in wavelengths become smaller, and ground-reflected energy tends to cancel direct-ray energy at the lower part of the common volume, where scattering efficiency is greatest. The frequency gain function $H_0$ in (9.1) is an estimate of the corresponding increase in transmission loss.

This function first decreases rapidly with increasing distance and then approaches a constant value. For $h_{te}/\lambda > 4 \, a/d$ and $h_{re}/\lambda > 4 \, a/d$, $H_0$ is negligible. The upper limit of $H_0$ as $h_{te}$ and $h_{re}$ approach zero is $H_0 = 6 + A_\omega \, \text{dB}$, where $A_\omega$ is the diffraction attenuation over a smooth earth, relative to free space, at $\theta = 0$. For frequencies up to 10 GHz, $A_\omega$ may be estimated from the CCIR Atlas of Ground Wave Propagation Curves [1955, 1959]. $H_0$ should rarely exceed 25 dB except for very low antennas.

The frequency gain function, $H_0$, depends on effective antenna heights in terms of wave lengths, path asymmetry, and the parameter $\eta_s$ shown on figure 9.2 and defined as

$$
\eta_s = 0.5696 \, h_0 \left[ 1 + (0.031 - 2.32 \, N_s \times 10^{-3} + 5.67 \, N_s^2 \times 10^{-6}) \exp(-3.8 \, h_0 \times 10^{-6}) \right] (9.3a)
$$

$$
h_0 = s \rho/(1 + s)^2 \text{ km.} \quad (9.3b)
$$

The parameters $r_1$ and $r_2$ are defined as

$$
r_1 = 4\pi \theta h_{te}/\lambda, \quad r_2 = 4\pi \theta h_{re}/\lambda \quad (9.4a)
$$

where $\theta$ is the angular distance in radians, and the effective antenna heights $h_{te}$, $h_{re}$ are in the same units as the radio wave length, $\lambda$. In terms of frequency $r_1$ and $r_2$ may be written

$$
r_1 = 41.92f h_{te}, \quad r_2 = 41.92f h_{re} \quad (9.4b)
$$

where $\theta$ is in radians, $f$ in MHz, and $h_{te}$, $h_{re}$ are in kilometers.

For the great majority of transhorizon paths, $s$ is within the range $0.7 \leq s \leq 1$. The effect of very small values of $s$, with $a_0 \ll \rho_0$, may be seen in figures III.15 to III.19, which have been computed for the special case where effective transmitting and receiving antenna heights are equal.
a) For $\eta_s \geq 1$:

Read $H_o(r_1)$ and $H_o(r_2)$ from figure 9.3; then $H_o$ is

$$H_o = \frac{H_o(r_1) + H_o(r_2)}{2} + \Delta H_o$$  \hfill (9.5)

where

$$\Delta H_o = 6 \left(0.6 - \log \eta_s\right) \log s \log q.$$

If $\eta_s > 5$ the value of $H_o$ for $\eta_s = 5$ is used. The correction term $\Delta H_o$ is zero for $\eta_s = 4$, $s = 1$, or $q = 1$ and reaches a maximum value, $\Delta H_o = 3.6$ db, for highly asymmetrical paths when $\eta_s = 1$. The value of $\Delta H_o$ may be computed as shown or read from the nomogram, figure 9.4. A straight line between values of $s$ and $q$ on their respective scales intersects the vertical line marked $\varnothing$. This point of intersection when connected by a straight line to the appropriate value of $\eta_s$ intersects the $\Delta H_o$ scale at the desired value.

The following limits should be applied in determining $\Delta H_o$:

- If $s \geq 10$ or $q \geq 10$, use $s = 10$ or $q = 10$.
- If $s \leq 0.1$ or $q \leq 0.1$, use $s = 0.1$ or $q = 0.1$.
- If $\Delta H_o \geq \frac{H_o(r_1) + H_o(r_2)}{2}$, use $H_o = H_o(r_1) + H_o(r_2)$.
- If $\Delta H_o$ would make $H_o$ negative, use $H_o = 0$.

b) For $\eta_s < 1$:

First obtain $H_o$ for $\eta_s = 1$ as described above, then read $H_o$ for $\eta_s = 0$ from figure 9.5. Figure 9.5b shows $H_o(\eta_s = 0)$ for the special case of equal antenna heights. The desired value is found by interpolation:

$$H_o(\eta_s < 1) = H_o(\eta_s = 0) + \eta_s[H_o(\eta_s = 1) - H_o(\eta_s = 0)].$$  \hfill (9.6)

The case $\eta_s = 0$ corresponds to the assumption of a constant atmospheric refractive index.

A special case, $h = h_0$, $r_1 = r_2$, occurs frequently in systems design. For this case $H_o$ has been plotted versus $r$ in figures III.15 to III.19 for $\eta_s = 1, 2, 3, 4, 5$ and for $s = 0.1, 0.25, 0.5, 0.75$ and 1. For given values of $\eta_s$ and $s$, $H_o$ is read directly from the graphs using linear interpolation. No correction term is required. For $\eta_s < 1$ the value of $H_o(\eta_s = 1)$ is read from figure 9.3 with $r_1 = r_2$ and $H_o(\eta_s = 0)$ is read from figure 9.5 as before.
9.3 The Scattering Efficiency Correction, $F_0$

The correction term $F_0$ in (9.1) allows for the reduction of scattering efficiency at great heights in the atmosphere:

$$F_0 = 1.086 \left( \frac{\eta_s}{h_o} \right) (h_o - h_1 - h_{Lt} - h_{Lt'}) \text{ db}$$  \hspace{1cm} (9.7)

where $\eta_s$ and $h_o$ are defined by (9.3) and $h_1$ is defined as

$$h_1 = s D_s (1 + s)^2, \quad D_s = d - d_{Lt} - d_{Lt'}$$  \hspace{1cm} (9.8)

The heights of the horizon obstacles, $h_{Lt}$, $h_{Lt'}$, and the horizon distances $d_{Lt}$, $d_{Lt'}$ are defined in section 6. All heights and distances are expressed in kilometers.

The correction term $F_0$ exceeds 2 decibels only for distances and antenna heights so large that $h_o$ exceeds $h_1$ by more than 3 kilometers.
9.4 Expected Values of Forward Scatter Multipath Coupling Loss

Methods for calculating expected values of forward scatter multipath coupling loss are given in several papers, by Rice and Daniel [1955], Booker and de Bettencourt [1955], Staras [1957], and Hartman and Wilkerson [1959]. This report uses the most general method available based on the paper by Hartman and Wilkerson [1959].

As explained in section 2, the path antenna gain is

\[ G_p = G_t + G_r - L_{gp} \text{ db} \]  \hspace{1cm} (9.9)

where \( G_t \) and \( G_r \) are free space antenna gains in decibels relative to an isotropic radiator. The influence of antenna and propagation path characteristics in determining the loss in path antenna gain or multipath coupling loss \( L_{gp} \) are interdependent and cannot be considered separately.

This section shows how to estimate only that component of the loss in path antenna gain which is due to phase incoherence of the forward scattered fields. This quantity is readily approximated from figure 9.6 as a function of \( \eta_s \), defined by (9.3), and the ratio \( \theta/\Omega \), where \( \Omega = 2\delta \) is the effective half-power antenna beamwidth. If the antenna beamwidths are equal, \( \Omega_t = \Omega_r \), and if \( s = 1 \), values of \( L_{gp} \) from figure 9.6 are exact. When antenna beamwidths are not equal the loss in gain may be approximated using \( \Omega = \sqrt{\Omega_t \Omega_r} \).

The relation between the free-space antenna gain \( G \) in decibels relative to an isotropic radiator and the half power beamwidth \( \Omega = 2\delta \) was given by (2.5) as:

\[ G = 3.50 - 20 \log \delta = 9.52 - 20 \log \Omega \text{ db} \]

where \( \delta \) and \( \Omega \) are in radians.

Assuming 56% aperture efficiencies for both antennas,

\[ \theta/\Omega \approx \theta(\Omega_t \Omega_r)^{-1/2} \approx 0.3350 \exp \{0.0576 [G_t + G_r]\} \]  \hspace{1cm} (9.10)

where \( \theta \) is the angular distance in radians and \( G_t, G_r \) are the free space gains in decibels.

Section 2 shows that the gain for parabolic dishes with 56% aperture efficiency may be computed as (2.7):

\[ G = 20 \log D + 20 \log f - 42.10 \text{ db} \]

where \( D \) is the diameter of the dish in meters and \( f \) is the frequency in MHz.

For dipole-fed parabolic antennas where \( 10 < D/\lambda < 25 \), an empirical correction gives the following equation for the antenna gain(2.8):

\[ G = 23.3 \log D + 23.3 \log f - 55.1 \text{ db} \]

9-6
The general method for calculating $L_{gp}$ requires the following parameters:

$$v = \eta_y / 2, \quad \mu = \delta / \delta_t$$

(9.11)

For $su \geq 1$, $n = \sigma / \delta_t$. For $su \leq 1$, $n = \beta_o / \delta_t$

(9.12a)

$$\delta = (n + 0.03v) / f(v)$$

(9.12b)

$$f(v) = \left[ 1.36 + 0.116v \right] \left[ 1 + 0.36 \exp(-0.56v) \right]^{-1}$$

(9.13)

where $\eta_y$, $s$, $\sigma_o$, and $\beta_o$ have been defined, $\delta_t$ and $\delta_r$ are the effective half-power semi-beamwidths of the transmitting and receiving antennas, respectively, and $f(v)$ as defined by (9.13) is shown on figure 9.7.

Figure 9.8 shows $L_{gp}$ versus $\delta$ for various values of the product $su$. For $su < 1$ read figure 9.8 for $1/(su)$ instead of $su$.

9.5 Combination of Diffraction and Scatter Transmission Loss

For transmission paths extending only very slightly beyond line-of-sight, diffraction will be the dominant mechanism in most cases and scattering may be neglected. Conversely, for long paths, the diffracted field may be hundreds of decibels weaker than the scattered field, and thus the diffraction mechanism can be neglected. In intermediate cases, both mechanisms have to be considered and the results combined in the following manner:

Figure 9.9 shows a function, $R(0.5)$, which depends on the difference between the diffraction and scatter transmission loss. Calculate this difference $(L_{dr} - L_{sr})$ in decibels, determine $R(0.5)$ from figure 9.9 and then determine the resulting reference value of hourly median transmission loss, $L_{cr}$, from the relation

$$L_{cr} = L_{dr} - R(0.5).$$

(9.14)

If the difference between the diffracted and the scattered transmission loss values exceeds 15 dB, the resulting value of $L_{cr}$ will be equal to $L_{dr}$ if it is smaller than $L_{sr}$, or to $L_{sr}$ if this is the smaller value. In general, for most paths having an angular distance greater than 0.02 radians the diffraction calculations may be omitted; in this case, $L_{cr} = L_{sr}$.
9.6 An Example of Transmission Loss Predictions for a Transhorizon Path

Predicted forward scatter and diffraction losses are computed for a 283 km path from Dallas to Austin, Texas. The prediction is compared with measurements at a frequency of 104.5 MHz. Figure 9.10 shows the great circle profile of this path, obtained by the methods of section 6, plotted on a linear scale with allowance for the sea level curvature. The vertical scale in the figure is much exaggerated to show some of the detail of terrain.

The effective earth's radius is determined as described in section 4. From figure 4.1 minimum monthly values of \( N_o \) are read at approximate horizon locations. Appropriate terrain heights are used in (4.3) to compute horizon values of \( N_s \), whose average is \( N_s = 306 \). From (4.4) the effective earth's radius is then 8580 km.

A reference value, \( L_{cr} \), of basic transmission loss, which corresponds to winter afternoon conditions, is computed as shown below. For each parameter the appropriate equation or figure is referenced.

Path: Dallas to Austin, Texas
\[ d = 283.1 \text{ km}, \ f = 104.5 \text{ MHz}, \ N_s = 306, \ a = 8580 \text{ km} \]

| Parameter \( h_s, h_r \) | Transmitter \( 280.4 \text{ m} \) | Receiver \( 243.9 \text{ m} \) | Reference figure 9.10 | \( h_s, h_r \) | Transmitter \( 135.0 \text{ m} \) | Receiver \( 9.8 \text{ m} \) | \( (6.11) \) and \( (6.12) \) | \( h_s, h_r \) | Transmitter \( 219.5 \text{ m} \) | Receiver \( 274.3 \text{ m} \) | Reference figure 9.10 | \( d_L, d_r \) | Transmitter \( 39.6 \text{ km} \) | Receiver \( 8.8 \text{ km} \) | figure 9.10 | \( \theta, \gamma \) | Transmitter \( -3.845 \text{ mr} \) | Receiver \( +2.933 \text{ mr} \) | \( (6.15) \) | \( a, \beta \) | Transmitter \( 12.777 \text{ mr} \) | Receiver \( 19.296 \text{ mr} \) | \( (6.18) \) | \( \alpha, \beta \) | Transmitter \( 0.768 \text{ mr} \) | Receiver \( 3.961 \text{ mr} \) | \( (6.16) \) | \( d_s, d_r \) | Transmitter \( 130.72 \text{ km} \) | Receiver \( 103.95 \text{ km} \) | \( (6.20) \) | \( \Delta \alpha, \Delta \beta \) | Transmitter \( 0.057 \text{ mr} \) | Receiver \( 0.021 \text{ mr} \) | Figure 6.9 | \( a, \beta \) | Transmitter \( 12.834 \text{ mr} \) | Receiver \( 19.317 \text{ mr} \) | \( (6.19) \)

The angular distance \( \theta = 32.151 \text{ mr} = 0.032151 \text{ radians} \) and the product \( \theta d \) is 9.10. The ratio of \( a/\beta \) is 0.664. Then the function \( F(\theta d) \) from figure 9.1 or figures III.12 and III.13 is \( F(\theta d) = 167.0 \text{ db} \). From (9.3) the height \( h_o = 2.18 \text{ km} \), and \( \eta_s = 1.06 \). From (9.4) and figure 9.3 the parameters \( r_1 = 19.01, H_o(r_1) = 0.15 \text{ db}, r_2 = 13.5, \) and \( H_o(r_2) = 13.5 \text{ db} \). From figure 9.4 and (9.5) \( \Delta H_o = 0.61 \text{ db} \) and \( H_o = 7.40 \text{ db} \). The correction term \( \Delta \alpha \) defined by (9.7) is negligible. Figure 3.6 shows that the allowance for absorption \( A_a = 0.01 \text{ db} \).

The reference value \( L_{bsr} \) of long-term median basic transmission loss due to forward scatter given by (9.1) is then
30 \log f = 60.573 \\
20 \log d = 49.038 \\
F(9d) = 167.0 \quad \text{figure 9.1} \\
F' = 0 \quad (9.7) \\
H' = 7.40 \quad (9.5) \\
A_a = 0.01 \quad \text{figure 3.6}

and \( L_{bsr} = 186 \text{ db} \).

Although this is almost certainly a scatter path, the diffraction loss for a transhorizon path is computed as an example. For horizontal polarization over average ground figures 8.1 and 8.2 show \( K(a = 8497) = 0.001 \) and \( b = 93^\circ \). The following additional parameters are computed:

\[
\begin{align*}
\text{Reference} & \quad \text{Parameter} \\
(8.8) & \quad a_1 = 5808 \text{ km} \\
(8.9) & \quad a_2 = 3951 \text{ km} \\
(8.13) & \quad a_t = 9179 \text{ km} \\
(8.13) & \quad a_r = 5804 \\
(8.13) & \quad C_1 = 1.135 \\
(8.13) & \quad C_2 = 1.291 \\
(8.13) & \quad C_3 = 0.975 \\
(8.13) & \quad C_4 = 1.136 \\
(8.13) & \quad K_1 = 0.001135 \\
(8.13) & \quad K_2 = 0.0001291 \\
(8.13) & \quad K_t = 0.000975 \\
(8.13) & \quad K_r = 0.001136 \\
(8.13) & \quad B_1 = 1.6059 \\
(8.13) & \quad B_2 = 1.6058 \\
(8.13) & \quad B_t = 1.6062 \\
(8.13) & \quad B_r = 1.6059 \\
(8.13) & \quad C_1(K_1) = 20.03 \\
(8.13) & \quad C_1(K_2) = 20.03 \\
(8.13) & \quad C_1(K_1, 2) = 20.03 \\
(8.13) & \quad x_1 = 385.85 \\
(8.13) & \quad x_2 = 112.25 \\
(8.13) & \quad x_t = 2452.37 \\
(8.13) & \quad x_r = 107.14 \\
\end{align*}
\]

Then from (8.10) the attenuation relative to free space \( A = 132.61 + A_a = 132.62 \text{ db} \).

The free space loss (2.16) is \( L_{bsf} = 121.87 \text{ db} \) and the long-term median median transmission loss due to diffraction \( L_{bd} = 254.5 \text{ db} \). As expected this is much more than the predicted scatter loss and the long-term reference value \( L_{cr} = L_{bsr} = 186 \text{ db} \).

Long-term variability of hourly median basic transmission loss over this path may be computed using the methods described in section 10. An "effective" distance, \( d_e \), is computed using (10.3). The appropriate value of \( V(0.5, d_e) \) is read from figure III.32 of annex III, and subtracted from \( L_{cr} \) to obtain the long-term median transmission loss.

Variability about the median is then determined as a function \( Y(q, d_e) \). The effective distance \( d_e \) is computed using (10.1), (10.2) and (10.3b). \( d_e = 64.0 \text{ km} \), \( d_e = 62.6 \text{ km} \), and \( d_e = 286.4 \text{ km} \). From figures 10.14, 10.15, III.32 and from (10.6) the following parameters are:

\[
\begin{align*}
\text{Parameter} & \quad \text{Summer} & \quad \text{Winter} & \quad \text{All Hours} & \quad \text{Reference} \\
V(0.5, d_e) & \quad 5.0 & \quad 1.0 & \quad 3.0 & \quad \text{figure III.32} \\
Y(0.1, d_e, 100 \text{ MHz}) & \quad 7.75 & \quad 7.05 & \quad 7.75 & \quad \text{figure 10.14} \\
Y(0.9, d_e, 100 \text{ MHz}) & \quad 6.35 & \quad -6.35 & \quad -6.35 & \quad \text{figure 10.14} \\
g(0.1, f) & \quad 1.055 & \quad 1.055 & \quad 1.055 & \quad \text{figure 10.15} \\
g(0.9, f) & \quad 1.055 & \quad 1.055 & \quad 1.055 & \quad \text{figure 10.15} \\
Y(0.1) & \quad 8.18 & \quad 7.44 & \quad 8.18 & \quad (10.6) \\
Y(0.9) & \quad -6.70 & \quad -6.70 & \quad -6.70 & \quad (10.6)
\end{align*}
\]
Using the reference value $L_{cr} = 186\text{ db}$ and the ratios given in (10.7) the predicted cumulative distributions for summer, winter and all hours are tabulated below:

</table>

These cumulative distributions are shown graphically on figure 9.11 together with distributions derived from measurements over the path. The data represent more than 23,000 hourly medians from measurements over a period of more than 3 years. The arrows on the curves at 0.001 indicate that losses were less than the values plotted while those at 0.99 and 0.999 indicate that the losses were greater than the values plotted.

An example may be included here of the method of mixing distributions described in subsection III.7.2. The summer and winter distributions of data may be mixed in order to obtain the distribution of hourly median values for all hours. Several levels of transmission loss from 165 to 195 db are chosen and the value $q$ is read from figure 9.11 for each distribution. A weighted average is then obtained at each level to provide the mixed distribution of data corresponding to all hours. The weights are the number of hours of data in each case and the weighted average is $\frac{1}{23,294} (q \times 12,160 + q \times 11,134)$.

BASIC TRANSMISSION LOSS IN DECIBELS

Figure 9.11
10. LONG-TERM POWER FADING

The variability of tropospheric radio transmission loss depends upon changes in the atmosphere and upon complex interrelationships between various propagation mechanisms. Short-term variability or 'phase interference fading," associated with simultaneously occurring modes of propagation, is discussed in annex V. The effects of this type of fading expected within an hour are allowed for by determining an hourly median rms-carrier-to-rms-noise ratio which defines the grade of service that will be provided. Long-term power fading, identified with the variability of hourly median values of transmission loss, is usually due to slow changes in average atmospheric refraction, in the degree of atmospheric stratification, or in the intensity of refractive index turbulence.

An estimate of the long-term power fading to be expected over a given path is important to insure adequate service over the path. The possibility that unusually high interfering fields may occur for an appreciable fraction of time places restrictions on services operating on the same or adjacent frequencies. The basis for the mainly empirical predictions of long-term variability given here needs to be well understood in order to appreciate their value as well as their limitations.

An increase in atmospheric refraction increases long distance diffraction or forward scatter fields but may lead to multipath fading problems over short paths. Increased turbulence of the atmosphere may result in either an increase or a decrease of radio transmission loss depending on the geometry of a particular path and on the dominance of various propagation mechanisms. Increased stratification favors propagation by reflection from elevated layers and sometimes the guiding of energy by ducts or layers. Such stratification usually increases long-distance fields but may be associated with prolonged fadeouts at short distances.

Just beyond radio line-of-sight, fading rate and fading range depend in a very complex manner on the relative importance of various propagation mechanisms. During periods of layering and ducting in the atmosphere, transmission loss shows a tendency to go into relatively deep fades, with durations from less than a minute to more than an hour. Ordinarily a diffraction signal fades slowly if at all, and the fades are of relatively short duration and very deep. A tropospheric forward scatter signal, on the other hand, exhibits the rapid and severe fading characteristic of the Rayleigh distribution. An intermediate type of fading results when the scattered power is nearly equal to power introduced by some mechanism such as diffraction, for which the variation in time is usually very slow. Aircraft reflections introduce rapid, intense, and relatively regular fading. Meteor bursts and some types of ionospheric propagation add spikes to a paper chart record.

Space-wave fadeouts [Bean, 1954] may represent power fading due to defocusing of radio energy in some regions of space, (radio holes) accompanied by a focusing effect and
signal enhancement in other regions [Doherty, 1952; Price, 1948], or may correspond to phase interference fading phenomena. In temperate continental climates, space-wave fadeouts are likely to occur primarily at night and most frequently during the summer months; they are more frequent at UHF than at VHF, and their occurrence can be correlated with the occurrence of ground-modified refractive index profiles [Barsis and Johnson, 1962]. Such fading predominates in geographic areas where layers and ducts occur frequently. Ordinary space diversity does not appear to be helpful in overcoming this type of fading. During periods of uniform refractive-index lapse rates, prolonged fadeouts are much less intense or do not exist. Sometimes those that do exist are caused by multipath reflections which arrive in such a phase and amplitude relationship that a slight change in the lapse rate will cause a large change in the resultant field. The latter type can be overcome in most instances by either relocating the terminal antennas or by the use of space diversity.

General discussions of the time fading of VHF and UHF radio fields will be found in reports by Bullington [1950], du Castel [1957a], Chernov [1955], Grosskopf [1958], Krasil'nikov [1949], Troitski [1957b], and Ugai [1961]. Silverman [1957], discusses some of the theory of the short-term fading of scatter signals, Bremmer [1957] discusses signal distortion due to tropospheric scatter, while Beckmann [1961b] considers related depolarization phenomena.

The observed correlation of radio data with various meteorological parameters is discussed by Bean [1956, 1961], Bean and Cahoon [1957], du Castel and Misme [1957], Josephson and Blomquist [1958], Misme [1958, 1960a, b, c, 1961], Molér and Holden [1960], and Ryde [1946]. Meteorological parameters such as surface refractivity and the height gradient of refractive index have been found more useful as a basis for predicting regional changes than for predicting diurnal or seasonal variations. In this report meteorological information has been used to distinguish between climatic regions, while radio data are depended on to predict long-term variability about the computed long-term median value in each of these regions.

The basic data used in developing these estimates of long-term power fading were recorded in various parts of the world over more than a thousand propagation paths. Path distances extend from within line-of-sight to about 1000 kilometers, and frequencies range from 40 MHz to 10 GHz.

As more data are collected, particularly in regions where little information is currently available, these estimates should be re-examined and revised. Allowances should sometimes be made for predictable long-term variations in antenna gain, interference due to reflections from aircraft or satellites, and variations in equipment performance. Microwave attenuation due to rainfall, discussed in section 3, should be allowed for in estimating
the variability of transmission loss at frequencies above 5 GHz. The long-term variability of oxygen and water vapor absorption may be important above 15 GHz.

It is often desirable to specify rather precisely the conditions for which an estimate of power fading characteristics is desired. For instance, the average frequency dependence of long-term variability over a given type of profile depends critically on the relative dominance of various propagation mechanisms, and this in turn depends on climate, season, time of day, and average terrain characteristics. When it becomes possible to describe the actual inhomogeneous, stratified, and turbulent atmosphere more adequately, it should also be found worthwhile to "mix" predicted cumulative distributions of transmission loss for a variety of propagation mechanisms.

Three important effects of the atmosphere on radio propagation are considered. The amount a radio ray is bent and the intensity of atmospheric turbulence are usually correlated with the surface refractivity, \( N_s \). The intensity and stability of various types of stratification in the atmosphere are often not well correlated with \( N_s \). Rough terrain and high winds both tend to increase mixing in the atmosphere and consequently reduce the occurrence of superrefractive layers.
10.1 Effects of Atmospheric Stratification

Ground-based superrefractive layers tend to trap radio energy which is propagated within the layer in a manner similar to that in a waveguide. A "normal" gradient of refractive index at the surface of the ground is about -50 N/km, a ground-based superrefractive layer has a gradient from -100 to -157 N/km. Surface layers with stronger negative refractive index gradients may form ducts in which radio energy is refracted to such a degree that it follows the curvature of the earth. If a radio beam is elevated above a minimum angle, usually less than half a degree, the energy penetrates and escapes the duct.

If a transmitter radiating energy in a horizontal direction is located in a duct, the theoretical radio horizon distance over a smooth spherical earth would be infinite. On the other hand in a layer with a subrefractive gradient, (positive values of refractive index gradient) the energy is refracted upwards and the corresponding horizon distance may be much less than that with a normal gradient. For example, a transmitting antenna 50 m above a smooth earth would have a radio horizon distance of about 30 km with a "normal" gradient of about -50 N/km, but the horizon distance might be as little as 8 km under subrefractive conditions or as much as 3 to 5 times the normal distance in a ground-based duct. Such changes would result in marked variations in corresponding values of transmission loss.

The minimum radio frequency that may be trapped by a duct depends on its total thickness and the average refractive index gradient within it. Rather thick, strong ducts will trap frequencies of 300 MHz or less, somewhat weaker and thinner ducts will trap higher frequencies. Frequencies as low as 30 MHz would rarely be trapped. A duct that traps frequencies of about 1000 MHz will guide higher frequencies even more strongly while lower frequencies will exhibit greater attenuation or may not be trapped at all.

It is difficult to predict the fraction of time that high fields due to ducting conditions may be expected to occur. Figures 10.1 to 10.12, which are reproduced from a World Atlas of Atmospheric Radio Refractivity by Bean, Cahoon, Samson and Thayer [1966], show the percentage of time ground-based ducts may occur. These maps are based on radiosonde data recorded at about 100 weather stations, usually for a period of 5 years. The months of February, May, August and November were selected as representative of the seasons. Unfortunately few stations recorded profiles more than once a day so no information on diurnal trends is included. These maps show for frequencies of 300, 1000 and 3000 MHz the percentage of observations in each of the four "seasonal" months that trapping of radio waves may be expected to occur. Such maps indicate general or regional conditions but more information would be required for detailed local predictions.

In large areas of the world, primarily over temperate oceans and arctic areas, the incidence of ducting is less than one percent. Strong ground-based ducts are most common in tropical and subtropical regions from 0° to 30° north latitude, especially in western coastal areas and the Persian Gulf. Strong ducting conditions, for frequencies of 3000 MHz and above and centered on the Persian Gulf may occur as much as 75 percent of the time in
August and only 10 percent of the time in February. In contrast to this on the west coast of Africa, about 15° north latitude, ducting conditions occur about 50 percent of the time in February and November and only 20 to 30 percent of the time in the summer months. Strong subrefractive conditions, with corresponding increased transmission loss, may occur more than 2 percent of the time in tropical Africa, the east coast of South America, the eastern Mediterranean, southeastern Asia and northern Australia.

Some of the better-known maritime areas of superrefraction were listed by Booker [1946]. These include the west coasts of Africa and India, the northern part of the Arabian sea especially around the Persian Gulf in summer, and the northern part of Australia. Particularly during summer months ducting conditions occur in Atlantic coastal areas of Europe, the eastern Mediterranean, the Pacific Coastal areas of China, and in Japan. These early observations of the occurrence of ducting conditions are reflected in the series of world-wide maps, figures 10.1 to 10.12. It is apparent that the most intense superrefraction is encountered in tropical climates, in trade wind areas, and in most of the principal deserts of the world.

High fields due to ground-based ducts are essentially a fine weather phenomenon. Inland, during fine weather, ducting is most noticeable at night. Over the sea ducting is most marked where the warm dry air of an adjacent land-mass extends out over a comparatively cool sea. Areas of divergence, which favor elevated duct formation, appear to be most persistent over ocean areas from 10° to 40° north and south latitudes, especially during winter months. [Moler and Holden, 1960; Randall, 1964]. Elevated ducts are usually less important than ground-based ducts for tropospheric propagation.
10.2 Climatic Regions

Climatic regions may be defined in several different ways: (1) by geographic areas on a map, (2) by average meteorological conditions, (3) by the predominance of various propagation mechanisms or (4) by averages of available data. In various so-called "climates," at different times of day or seasons of the year, different propagation mechanisms may be dominant. For example, in a continental temperate climate the characteristics of a received signal over a given path may be quite different in the early morning hours in May than during the afternoon hours in February.

Based on our current knowledge of meteorological conditions and their effects on radio propagation, the International Radio Consultative Committee [CCIR 1963f] has defined several "climates." A large amount of data is available from continental temperate and maritime temperate climates. Other climatic regions, where few data are available, are discussed in annex III. The division into radio climates is somewhat arbitrary, based on present knowledge of radio meteorology, and is not necessarily the same as the division into meteorological climates [Haurwitz and Austin, 1944].

World maps of minimum monthly mean $N_0$, figure 4.1, and of the annual range of monthly mean $N$ figure III.31, may be useful in deciding which climate or climates are applicable in a given region. The boundaries between various climatic regions are not well defined. In some cases it may be necessary to interpolate between the curves for two climates giving additional weight to the one whose occurrence is considered more likely.

Some important characteristics of the climatic regions for which estimates of time variability are shown, are noted below:

1. **Continental Temperate** characterized by an annual mean $N_s$ of about 320 N-units with an annual range of monthly mean $N_s$ of 20 to 40 N-units. A continental climate in a large land mass shows extremes of temperature in a "temperate" zone, such as 30° to 60° north or south latitude. Pronounced diurnal and seasonal changes in propagation are expected to occur. On the east coast of the United States the annual range of $N_s$ may be as much as 40 to 50 N-units due to contrasting effects of arctic or tropical maritime air masses which may move into the area from the north or from the south.

2. **Maritime Temperate Overland** characterized by an annual mean $N_s$ of about 320 N-units with a rather small annual range of monthly mean $N_s$ of 20 to 30 N-units. Such climatic regions are usually located from 20° to 50° north or south latitude, near the sea, where prevailing winds, unobstructed by mountains, carry moist maritime air inland. These conditions are typical of the United Kingdom, the west coasts of North America and Europe and the northwestern coastal areas of Africa.

Although the islands of Japan lie within this range of latitude the climate differs in showing a much greater annual range of monthly mean $N_s$, about 60 N-units, the prevailing winds have traversed a large land mass, and the terrain is rugged. One would therefore not expect to find radio propagation conditions similar to those in the United Kingdom although
the annual mean \( N_s \) is 310 to 320 N-units in each location. Climate 1 is probably more appropriate than climate 2 in this area, but ducting may be important in coastal and over-sea areas of Japan as much as 5 percent of the time in summer.

3. **Maritime Temperate Oversea** coastal and oversea areas with the same general characteristics as those for climate 2. The distinction made is that a radio path with both horizons on the sea is considered to be an oversea path; otherwise climate 2 is used. Ducting is rather common for a small fraction of time between the United Kingdom and the European Continent, and along the west coast of the United States and Mexico.

4. **Maritime Subtropical Overland** characterized by an annual mean \( N_s \) of about 370 N-units with an annual range of monthly mean \( N_s \) of 30 to 60 N-units. Such climates may be found from about 10° to 30° north and south latitude, usually on lowlands near the sea with definite rainy and dry seasons. Where the land area is dry radio-ducts may be present for a considerable part of the year.

5. **Maritime Subtropical Oversea** conditions observed in coastal areas with the same range of latitude as climate 4. The curves for this climate were based on an inadequate amount of data and have been deleted. It is suggested that the curves for climates 3 or 4 be used, selecting whichever seems more applicable to each specific case.

6. **Desert, Sahara** characterized by an annual mean \( N_s \) of about 280 N-units with year-round semiarid conditions. The annual range of monthly mean \( N_s \) may be from 20 to 80 N-units.

7. **Equatorial** a maritime climate with an annual mean \( N_s \) of about 360 N-units and annual range of 0 to 30 N-units. Such climates may be observed from 20°N to 20°S latitude and are characterized by monotonous heavy rains and high average summer temperatures. Typical equatorial climates occur along the Ivory Coast and in the Congo of Africa.

8. **Continental Subtropical** typified by the Sudan and monsoon climates, with an annual mean \( N_s \) of about 320 N-units and an annual range of 60 to 100 N-units. This is a hot climate with seasonal extremes of winter drought and summer rainfall, usually located from 20° to 40°N latitude.

A continental polar climate, for which no curves are shown, may also be defined. Temperatures are low to moderate all year round. The annual mean \( N_s \) is about 310 N-units with an annual range of monthly mean \( N_s \) of 10 to 40 N-units. Under polar conditions, which may occur in middle latitudes as well as in polar regions, radio propagation would be expected to show somewhat less variability than in a continental temperate climate. Long-term median values of transmission loss are expected to agree with the reference values \( L_{cr} \).

High mountain areas or plateaus in a continental climate are characterized by low values of \( N_s \) and year-round semiarid conditions. The central part of Australia with its hot dry desert climate and an annual range of \( N_s \) as much as 50 to 70 N-units may be intermediate between climates 1 and 6.
Prediction of long-term median reference values of transmission loss, by the methods of sections 3 to 9, takes advantage of theory in allowing for the effects of path geometry and radio ray refraction in a standard atmosphere. Meteorological information is used to distinguish between climatic regions. Median values of data available in each of these regions are related to the long-term reference value by means of a parameter $V(0.5, d_e)$ which is a function of an "effective distance," $d_e$, defined below. Long-term fading about the median for each climatic region is plotted in a series of figures as a function of $d_e$. For regions where a large amount of data is available, curves are presented that show frequency-related effects. (Seasonal and diurnal changes are given in annex III for a continental temperate climate.)

10.3 The Effective Distance, $d_e$

Empirical estimates of long-term power fading depend on an effective distance, $d_e$, which has been found superior to other parameters such as path length, angular distance, distance between actual horizons, or distance between theoretical horizons over a smooth earth. The effective distance makes allowance for effective antenna heights and some allowance for frequency.

Define $\theta_{s_1}$ as the angular distance where diffraction and forward scatter transmission loss are approximately equal over a smooth earth of effective radius $a = 9000$ kilometers, and define $d_{s_1}$ as $9000 \theta_{s_1}$. Then:

$$d_{s_1} = 65 \left(\frac{100}{f}\right)^{1/3} \text{ km.}$$  \hfill (10.1)

The path length, $d$, is compared with the sum of $d_{s_1}$ and the smooth-earth distances to the radio horizons:

$$d_L = 3\sqrt{2h_{te}} + 3\sqrt{2h_{re}} \text{ km},$$  \hfill (10.2)

where the effective antenna heights $h_{te}$ and $h_{re}$ are expressed in meters and the radio frequency $f$ in MHz.

It has been observed that the long-term variability of hourly medians is greatest on the average for values of $d$ only slightly greater than the sum of $d_{s_1}$ and $d_L$. The effective distance $d_e$ is arbitrarily defined as:

- for $d \leq d_L + d_{s_1}$, $d_e = 130 d / (d_L + d_{s_1})$ \hfill (10.3a)

- for $d > d_L + d_{s_1}$, $d_e = 130 + d - (d_L + d_{s_1})$ \hfill (10.3b)

10-8
The Functions $V(0.5, d_e)$ and $Y(q, d_e)$

The predicted median long-term transmission loss for a given climatic region $L_n(0.5)$, characterized by a subscript $n$, is related to the calculated long-term reference value $L_{cr}$ by means of the function $V(0.5, d_e)$

$$L_n(0.5) = L_{cr} - V_n(0.5, d_e) \text{ dB}$$

where $L_n(0.5)$ is the predicted transmission loss exceeded by half of all hourly medians in a given climatic region. $V_n(0.5, d_e)$ is shown on figure 10.13 for several climates as a function of the effective distance $d_e$. For the special case of forward scatter during winter afternoons in a temperate continental climate, $V(0.5) = 0$ and $L(0.5) = L_{cr}$. In all other cases, the calculated long-term reference value $L_{cr}$ should be adjusted to the median $L_n(0.5)$ for the particular climatic region or time period considered. The function $F(6d)$ in the scatter prediction of a long-term reference median contains an empirical adjustment to data. The term $V(0.5, d_e)$ provides a further adjustment to data for all propagation mechanisms and for different climatic regions and periods of time.

In general, the transmission loss not exceeded for a fraction $q$ of hourly medians is

$$L_n(q) = L_n(0.5) - Y_n(q, d_e) \text{ dB}$$

where $Y_n(q, d_e)$ is the variability of $L_n(q)$ relative to its long-term median value $L_n(0.5)$. For a specified climatic region and a given effective distance, the cumulative distribution of transmission loss may be obtained from (10.5). In a continental temperate climate transmission loss is often nearly log-normally distributed. The standard deviation may be as much as twenty decibels for short transhorizon paths where the mechanisms of diffraction and forward scatter are about equally important. When a propagation path in a maritime temperate climate is over water, a log-normal distribution may be expected from $L(0.5)$ to $L(0.999)$, but considerably higher fields are expected for small fractions of time when pronounced superrefraction and ducting are present.
10.5 Continental Temperate Climate

Data from the U.S.A., West Germany, and France provide the basis for predicting long-term power fading in a continental temperate climate. More than half a million hourly median values of basic transmission loss recorded over some two hundred paths were used in developing these estimates.

Figure 10.14 shows basic estimates $Y(q, 100 \text{ MHz})$ of variability in a continental temperate climate. Curves are drawn for fractions 0.1 and 0.9 of all hours of the day for summer, winter and all year for a "typical" year. In the northern temperate zone, "summer" extends from May through October and "winter" from November through April.

A "frequency factor" $g(q, f)$ shown in figure 10.15 adjusts the predicted variability to allow for frequency-related effects:

$$Y(q) = Y(q, d, 100 \text{ MHz}) g(q, f).$$  (10.6)

The function $g(q, f)$ shows a marked increase in variability as frequency is increased above 100 MHz to a maximum at 400 to 500 MHz. Variability then decreases until values at 1 or 2 GHz are similar to those expected at 100 MHz. The empirical curves $g(q, f)$ should not be regarded as an estimate of the dependence of long-term variability on frequency, but represent only an average of many effects, some of which are frequency-sensitive. The apparent frequency dependence is a function of the relative dominance of various propagation mechanisms, and this in turn depends on climate, time of day, season, and the particular types of terrain profiles for which data are available. For example, a heavily forested low altitude path will usually show greater variability than that observed over a treeless high altitude prairie, and this effect is frequency sensitive. An allowance for the year-to-year variability is also included in $g(q, f)$. Data summarized by Williamson et al. [1960] show that $L(0.5)$ varies more from year to year than $Y(q)$. Assuming a normal distribution of $L$ within each year and of $L(0.5)$ from year to year, $L$ would be normally distributed with a median equal to $L(0.5)$ for a "typical" year. $Y(q)$ is then increased by a constant factor, which has been included in $g(q, f)$.

Estimates of $Y(0.1)$ and $Y(0.9)$ are obtained from figures 10.14, 10.15 and from equation 10.6. These estimates are used to obtain a predicted cumulative distribution using the following ratios:

$$Y(0.0001) = 3.33 Y(0.1) \quad Y(0.9999) = 2.90 Y(0.9)$$
$$Y(0.001) = 2.73 Y(0.1) \quad Y(0.999) = 2.41 Y(0.9)$$
$$Y(0.01) = 2.00 Y(0.1) \quad Y(0.99) = 1.82 Y(0.9)$$

For example, assume $f = 100 \text{ MHz}$, $d = 112 \text{ km}$, and a predicted reference median basic transmission loss, $L_{bcr} = 179 \text{ db}$, so that $Y(0.5, d) = 0.9 \text{ db}$, (figure 10.13), $Y(0.1, d_e, 100 \text{ MHz}) = 8.1 \text{ db}$, and $Y(0.9, d_e, 100 \text{ MHz}) = -5.8 \text{ db}$, (figure 10.14). $g(0.1, f) = g(0.9, f) = 1.05$ (figure 10.15). Then $Y(0.1) = 1.05 Y(0.1, d_e, 100 \text{ MHz}) = 8.5 \text{ db}$, and $Y(0.9) = 1.05 Y(0.9, d_e, 100 \text{ MHz}) = -6.1 \text{ db}$. Using the ratios given above:
Y(0.0001) = 28.3, Y(0.001) = 23.2, Y(0.01) = 8.5,
Y(0.9999) = -17.7, Y(0.999) = -14.7, Y(0.99) = -11.1, Y(0.9) = -6.1.
The median value is

\[ L_b(0.5) = V(0.5) = 178.1 \text{ db} \]

and the predicted distribution of basic transmission loss is;
L(0.0001) = 149.8, L(0.001) = 154.9, L(0.01) = 161.1, L(0.1) = 169.6, L(0.5) = 178.1,
L(0.9) = 164.2, L(0.99) = 189.2, L(0.999) = 192.8 and L(0.9999) = 195.8 db.

These values are plotted as a function of time availability, q, on figure 10.16 and show
a complete predicted cumulative distribution of basic transmission loss.

For antennas elevated above the horizon, as in ground-to-air or earth-to-space communication, less variability is expected. This is allowed for by a factor \( f(\theta_h) \) discussed in
annex III. For transhorizon paths \( f(\theta_h) \) is unity and does not affect the distribution. For
line-of-sight paths \( f(\theta_h) \) is nearly unity unless the angle of elevation exceeds 0.15 radians.

Allowance must sometimes be made for other sources of power fading such as attenuation
due to rainfall or interference due to reflections from aircraft that may not be ade-
quately represented in available data. For example, at microwave frequencies the distribution
of water vapor, oxygen, rain, snow, clouds and fog is important in predicting long-term
power fading. Let \( Y_1, Y_2, \ldots, Y_n \) represent estimates corresponding to each of these
sources of variability, and let \( \rho_{ij} \) be the correlation between variations due to sources \( i \) and \( j \). Then the total variability is approximated as:

\[ Y^2(q) = \sum_{i=1}^{m} Y_i^2(q) + 2 \sum_{i<j}^{m} Y_i Y_j \rho_{ij} \]

where \( Y(q) \) is positive for \( q < 0.5 \), zero for \( q = 0.5 \), and negative for \( q > 0.5 \). Section 3
shows how to estimate \( Y_a(q) \) and \( Y_r(q) \) for atmospheric absorption by oxygen and water
vapor, and for rain absorption respectively. Let \( \rho_{ia} \) be the correlation between variations
\( Y \) of available data and variations \( Y_a \) due to microwave absorption by oxygen and water
vapor. Let \( \rho_{ir} \) be the correlation between \( Y \) and \( Y_r \). Assuming that \( \rho_{ia} = 1, \rho_{ir} = 0.5, \)
and \( \rho_{ar} = 0, \)

\[ Y^2(q) = (Y + Y_a)^2 + Y_r^2 + Y Y_r \]

This method was used to allow for the effects of rainfall at frequencies above 5 GHz for
fractions 0.99 and 0.9999 of all hours in figures 1.6 to 1.11 of annex I.
Figures 10.17 to 10.22 show variability, $Y(q)$, about the long-term median value as a function of $d_e$ for period of record data in the following frequency groups: 40-88, 88-108, 108-250, 250-450, 450-1000, and > 1000 MHz. The curves on the figures show predicted values of $Y(q)$ for all hours of the year at the median frequency in each group. These medians are: 47.1, 98.7, 192.8, 417, 700, and 1500 MHz for data recorded in a continental temperate climate. Equation (10.6) and figures 10.14 and 10.15 were used to obtain the curves in figures 10.17 to 10.22.

An analytic function fitted to the curves of $V(0.5, d_e)$ and $Y(q, d_e, 100 \text{ MHz})$ is given in annex III. Diurnal and seasonal variations are also discussed and functions listed to predict variability for several times of day and seasons.

10.6 Maritime Temperate Climate

Studies made in the United Kingdom have shown appreciable differences between propagation over land and over sea, particularly at higher frequencies. Data from maritime temperate regions were therefore classified as overland and oversea, where oversea paths are categorized as having the coastal boundaries within their radio horizons. Paths that extend over a mixture of land and sea are included with the overland paths.

The data were divided into frequency groups as follows:

- Bands I and II (40-100 MHz)
- Band III (150-250 MHz)
- Bands IV and V (450-1000 MHz)

Long-term variability of the data for each path about its long-term median value is shown as a function of effective distance in figures 10.23 to 10.28. Curves were drawn through medians of data for each fraction of time $q = 0.0001, 0.001, 0.01, 0.1, 0.9, 0.99, 0.999, 0.9999$. Figures 10.23 to 10.28 show that it is not practical to use a formula like (10.6) for the maritime temperate climate, because the frequency factor $g(q, f)$ is not independent of $d_e$, as it is in the case of the continental temperate climate. The importance of tropospheric ducting in a maritime climate is mainly responsible for this difference.

These figures demonstrate greater variability oversea than overland in all frequency groups. The very high fields noted at UHF for small fractions of time are due to persistent layers and ducts that guide the radio energy. In cases of propagation for great distances over water the fields approach free space values for small fractions of time. Curves have been drawn for those distance ranges where data permitted reasonable estimates. Each curve is solid where it is well supported by data, and is dashed for the remainder of its length.

10-12
10.7 Other Climates

A limited amount of data available from other climatic regions has been studied, [CCIR 1963f]. Curves showing predicted variability in several climatic regions are shown in annex III, figures III.25 to III.29.

At times it may be necessary to predict radio performance in an area where few if any measurements have been made. In such a case, estimates of variability are based on whatever is known about the meteorological conditions in the area, and their effects on radio propagation, together with results of studies in other climatic regions. If a small amount of radio data is available, this may be compared with predicted cumulative distributions of transmission loss corresponding to somewhat similar meteorological conditions. In this way estimates for relatively unknown areas may be extrapolated from what is known.

10.8 Variability for Knife-Edge Diffraction Paths

The variability of hourly medians for knife-edge diffraction paths can be estimated by considering the path as consisting of two line-of-sight paths in tandem. The diffracting knife-edge then constitutes a common terminal for both line-of-sight paths. The variability of hourly median transmission loss for each of the paths is computed by the methods of this section and characterized by the variability functions

\[ V_1(q) = V_1(0.5) + Y_1(q) \text{ } \text{db} \]
\[ V_2(q) = V_2(0.5) + Y_2(q) \text{ } \text{db} \]

During any particular hour, the total variability function \( V \) for the diffraction path would be expected to be the sum of \( V_1 \) plus \( V_2 \). To obtain the cumulative distribution of all values of \( V \) applicable to the total path a convolution of the individual variables \( V_1 \) and \( V_2 \) may be employed [Davenport and Root, 1958].

Assuming that \( V_1 \) and \( V_2 \) are statistically independent variables, their convolution is the cumulative distribution of the variable \( V = V_1 + V_2 \). The cumulative distribution of \( V \) may be obtained by selecting \( n \) equally-spaced values from the individual distributions of \( V_1(q) \) and \( V_2(q) \), calculating all possible sums \( V_k = V_{11} + V_{12} \) and forming the cumulative distribution of all values \( V_k \) obtained in this manner.

Another method of convolution that gives good results requires the calculation and ordering of only \( n \), instead of \( n^2 \), values of \( V \). As before \( V_1(q) \) and \( V_2(q) \) are obtained for \( n \) equally spaced percentages. Then one set is randomly ordered compared to the other so that the sums \( V = V_1 + V_2 \) are randomly ordered. The cumulative distribution of these sums then provides the desired convolution of \( V_1 \) and \( V_2 \). If the distribution of \( V_1 - V_2 \) is desired this is the convolution of \( V_1 \) and \( -V_2 \).

Computations required to estimate long-term variability over a knife-edge diffraction path are given in the example described in section 7.5.

12. LIST OF SYMBOLS AND ABBREVIATIONS

In the following list the English alphabet precedes the Greek alphabet, and lower-case letters precede upper-case letters. As a general rule, upper-case letters have been used for quantities expressed in decibels, for example $w_t$ is transmitter power in watts, and $W_t$ is transmitter power in decibels above one watt. When the upper-case symbol is the decibel equivalent of a lower-case symbol they are usually listed together. Symbols that are used only in an annex are defined at the end of the appropriate annex, in Volume 2.

Sometimes a symbol may be used in quite different contexts, in which case it is listed for each separate context. Subscripts are used to modify the meaning of symbols. The order is:

1. Symbol without a subscript $h$
2. Symbol with a subscript, (letter subscripts in alphabetical order followed by number subscripts in numerical order) $h_r$
3. Symbol as a special function $h(x)$
4. Abbreviations $ht$

Following each definition an equation number or section number is given to show the term in its proper context. Where applicable, reference is made to a figure.

Throughout the report, logarithms are to the base 10 unless otherwise noted.

- **$a$** Effective earth's radius, allowing for average radio ray bending near the surface of the earth, (4.4) figure 4.2.
- **$a_e$** An equivalent earth's radius which is the harmonic mean of the radii $a_t$ and $a_r$ , (7.10).
- **$a_r$** The radius of a circular arc that is tangent to the receiving antenna horizon ray at the horizon, and that merges smoothly with the corresponding arc through the transmitting antenna horizon, (8.9) figure 8.7.
- **$a_s$** Effective earth's radius factor corresponding to $D_s$, (8.15).
- **$a_t$** Radius of a circular arc that is tangent to the transmitting horizon ray at the horizon, and that merges smoothly with the corresponding arc through the receiving antenna horizon, (8.9) figure 8.7.
- **$a_x$** The axial ratio of the polarization ellipse of a plane wave, (2.11).
- **$a_{rx}$** The axial ratio of the polarization ellipse associated with the receiving pattern (2.11).
- **$a_o$** The actual earth's radius, usually taken to be 6370 kilometers, (4.4).
- **$a_1$** Radius of the circular arc that is tangent to the transmitting antenna horizon ray at the horizon, and that passes through a point $h_t$ kilometers below the transmitting antenna, (8.8) figure 8.7.
- **$a_2$** Radius of the circular arc that is tangent to the receiving antenna horizon ray at the horizon, and that passes through a point $h_r$ kilometers below the receiving antenna, (8.8) figure 8.7.
A Attenuation relative to free space, expressed in decibels, defined as the basic transmission loss relative to that in free space, (2.20).

A The long-term median attenuation of radio waves due to atmospheric absorption by oxygen and water vapor, section 3.

A For transhorizon paths, $A = A_a + A_{at}$, the sum of the absorption from the transmitter to the crossover of horizon rays and the absorption from the crossover of horizon rays to the receiver, section 3.

A Total absorption attenuation within a cloud, (3.13).

A Total absorption due to rainfall over a given path, (3.7).

A Rate of attenuation through woods in full leaf, (5.18).

A Diffraction attenuation relative to free space at an angular distance $\theta = 0$ over a smooth earth, section 9.2.

A(v, 0) Attenuation relative to free space as a function of the parameter $v$, (7.2) figure 7.1.

A(v, $p$) Diffraction attenuation relative to free space for an isolated perfectly conducting rounded obstacle, (7.7), figure 7.3.

A(0, $p$) The diffraction loss for $\theta = 0$ over an obstacle of radius $r$, (7.7) figure 7.4.

B The parameter $B(K, b)$ corresponding to the effective earth's radius $a$, (8.15).

B Values of the parameter $B(K, b)$ that correspond to values of $K_1, K_2, t, r$, (8.13).

B Defined by (8.2), (8.13) and (8.15) as the product of several factors, combined for convenience in computing diffraction attenuation.

B Any point along the great circle path between antenna terminals A and B, figure 6.3.

B A parameter plotted in figure 8.3 as a function of $K$ and $b^*$, (8.2).

c Free space velocity of radio waves, $c = 299792.5 \pm 0.3$ km/sec.

C The parameter $C(K, b)$ corresponding to $K_1$ and $K_2$, also written $C^K_1$ and $C^K_2$, (8.11).

C The weighted average of values of $C_{1}(K_1, b^*)$ and $C_{1}(K_2, b^*)$, (8.11).

CCIR International Radio Consultative Committee.

d Great circle propagation path distance, measured at sea level along the great circle path determined by two antenna locations, $A_1$ and $A_2$, figure 6.1.

d Clearing depth in meters, defined as the distance from the edge of woods to the lower antenna along a propagation path, (5.19).

d Effective propagation path distance, a function of $d, f_{mc}, h_{le}, h_{re}$, section 10.1, (10.3).

d The sum of the horizon distances $d_{LR}$ and $d_{LT}$. In section 10, $d_L$ is defined for a smooth spherical earth of radius 9000 km, (10.2) and (10.3).

d Great circle distances from the receiving and from the transmitting antennas to the corresponding horizons, figure 6.1.
\[ d_{sr}, d_{st} \] Distance between the receiving or transmitting antenna horizon and the crossover of horizon rays as measured at sea level, (6.20).

\[ d'_{sr}, d'_{st} \] If \( \theta \) or \( \theta' \) is negative, \( d'_{sr} \) or \( d'_{st} \) is computed (6.23) and substituted for \( d_{sr} \) or \( d_{st} \) in reading figure 6.9.

\[ d_{s1} \] The theoretical distance where diffraction and scatter fields are approximately equal over a smooth earth, (10.1).

\[ d_{o} \] The greatest distance for which the attenuation relative to free space is zero, (5.10).

\[ d_{1}, d_{2} \] Distance from the transmitting, or the receiving antenna, to the crossover of horizon rays, measured at sea level, figure 6.1.

\[ d_{1}, d_{2} \] Great circle distance from one antenna of a pair to the point of reflection of a reflected ray, figure 5.1.

\[ dB \] Decibels = \( 10 \log_{10} \) (power ratio) or \( 20 \log_{10} \) (voltage ratio). In this report, all logarithms are to the base 10 unless otherwise stated.

\[ dBu \] Decibels above one microvolt per meter.

\[ dBW \] Decibels above one watt.

\[ D \] Divergence coefficient, a factor used to allow for the divergence of energy due to reflection from a convex surface, (5.2).

\[ D \] Diameter of a parabolic reflector in meters, (2.7).

\[ D_{sr} \] Great circle distance between transmitting and receiving horizons, (6.17), figure 6.1.

\[ e_{c}, e_{p} \] The positive to negative amplitude of the cross-polarized vector component \( e_{c} \) and of the principal polarization component \( e_{p} \) of a complex polarization vector \( e \), section 2.3 and annex II.

\[ e \] A complex vector \( e = e_{p} + ie_{c} \), section 2.3 and annex II.

\[ f \] Radio wave frequency in megahertz (megacycles per second).

\[ f(\nu) \] A function used in computing path antenna gain, defined by (9.13) figure 9.7.

\[ F_{o} \] The correction term \( F_{o} \) allows for the reduction of scattering efficiency at great heights in the atmosphere, (9.1) and (9.7).

\[ F(x_{1}), F(x_{2}) \] Functions used in computing diffraction attenuation, (8.1) and figures 8.5 and 8.6.

\[ F(6d) \] The attenuation function used in calculating median basic transmission loss for scatter paths, (9.1) figures 9.1, and III.11 to III.14.

\[ g_{s}, g_{t}, G_{s}, G_{t} \] Maximum free space directive gains for the receiving and transmitting antennas respectively, \( G_{s} = 10 \log_{10} g_{s} \) db, \( G_{t} = 10 \log_{10} g_{t} \) db, section 2.2.

\[ g_{s1}, g_{s2} \] Directive gain factors defined for each antenna in the direction of the point of ground reflection, (5.1).

\[ g_{o} \] The maximum value of the operating gain of a receiving system, (V.7).

\[ \phi_{o} \] The directive gain for one antenna in the direction of the other, section 5.1.

\[ g_{o1}, g_{o2} \] The directive gain of the transmitting and receiving antennas, each in the direction of the other, assuming matched antenna polarizations, (5.1).
$g(p, f)$ A frequency factor used to adjust predicted long-term variability to allow for
frequency-related effects, (10.6) figure 10.3.

$g_t(\hat{f}), G_t(\hat{f})$ Free space directive gain of the transmitting antenna in the direction $\hat{f}$, see also
$g_t'(\hat{f}), G_t(\hat{f}) = 10 \log g_t(\hat{f})$ db, section 2.2.

$g_t'$ Power gain of a transmitting antenna when the power input to the antenna terminals
is $w_t$ watts, section 2.2.

$g_t'(\hat{f}), G_t'(\hat{f})$ Power gain of a transmitting antenna in the direction $\hat{f}$, $G_t'(\hat{f}) = 10 \log g_t'(\hat{f})$ db,
section 2.2.

$G$ The maximum free space directive gain relative to an isotropic radiator (2.5).

$G_p$ Path antenna gain, the change in transmission loss or propagation loss if hypothet-
cical loss-free isotropic antennas with no orientation, polarization, or multipath
coupling loss were used at the same locations at the actual antennas, (2.14).

$G_{pf}$ Path antenna gain in free space, (2.17).

$G_p$ Path antenna power gain, (2.14).

$GPP$ Residual height gain function, figure 7.1.

$G'(\hat{f})$ Power gain, in decibels, of a receiving antenna, (2.4).

$G(h)$ The function $G(h)$ for the transmitting and receiving antennas, respectively,
(7.5).

$G(\hat{f})$ Directive gain of an antenna in the direction $\hat{f}$. The maximum value of $G(\hat{f})$ is
$G$, section 2.2.

$G_r(\hat{f})$ Directive gain, in decibels, of a receiving antenna in the direction $\hat{f}$, (2.4).

$G(x_o)$ A function used in computing diffraction, (8.1) figures 8.5 and 8.6.

$GHz$ Radio frequency in gigacycles per second.

$h$ Height above the surface of the ground as used in (3.10), (3.12).

$h$ Height referred to sea level.

$h_l$ Equidistant heights of terrain above sea level, (5.15), (6.10).

$h_{Lr}, h_{Lt}$ Height of the receiver or transmitter horizon obstacle above sea level, (6.15).

$h_o$ Height of the intersection of horizon rays above a straight line between the antennas,
determined using an effective earth's radius, $a$, (9.3b) and figure 6.1.

$h_r, h_t$ The height $h_r$ or $h_t$ is defined as the height of the receiving or transmitting an-
tenna above the average height of the central 80% of the terrain between the an-
tenna and its horizon, or above ground, whichever gives the larger value, (6.11).

$h_{re}, h_{te}$ Effective height of the receiving or transmitting antenna above ground. For $h_r, h_t
less than one kilometer $h_{re} = h_r, h_{te} = h_t$. For higher antennas a correction $\Delta h$
is used, (6.12).

$h_{rs}, h_{ts}$ Height of the receiving antenna or transmitting antenna above sea level, figure 6.1,
(6.11), (6.15).

$h_s$ Elevation of the surface of the ground above mean sea level, (4.3).

$h_t$ The heights above sea level of evenly spaced terrain elevations between the trans-
mitter and its horizon, (6.11).
\(h_1\) Height of the crossover of horizon rays above a straight line between the transmitter and receiver horizon obstacles, (9.7) figure 6.1.

\(h_1', h_2\) Heights of antenna terminals 1 and 2 above the surface of the earth, figure 5.1.

\(h_1', h_2'\) Heights of antenna terminals 1 and 2 above a plane tangent to a smooth earth at the bounce point of a reflected ray, (5.8).

\(\bar{h}\) Average height above sea level, (5.15).

\(\bar{h}_t\) Average height of the transmitting antenna above the central 80% of terrain between the transmitter and its horizon, (6.11).

\(\bar{h}_t', \bar{h}_2\) Normalized heights of the transmitting and receiving antennas, (7.6).

\(h(x)\) A straight line fitted by least squares to equidistant heights above sea level, (5.15).

\(h(0), h(d)\) Height above sea level of a smooth curve fitted to terrain visible to both antennas, and extrapolated to the transmitter at \(h(0)\) and the receiver at \(h(d)\), (5.17).

\(h_1(x)\) A series of equidistant heights above sea level of terrain visible to both antennas, section 5.1.

\(H_0\) The frequency gain function, discussed in section 9.2.

\(H_0(\eta_s < 1), H_0(\eta_s = 1)\) Value of the frequency gain function, \(H_0\), where the parameter \(\eta_s\) is less than or equal to one, respectively, (9.6).

\(H_0(\eta_s = 0)\) The frequency gain function when \(\eta_s = 0\) which corresponds to the assumption of a constant atmospheric refractive index, figure 9.5.

\(Hz\) Abbreviation for hertz = cycle per second.

\(K\) A frequency-dependent coefficient, (3.8).

\(K\) A parameter used in computing diffraction attenuation, \(K\) is a function of the effective earth's radius, carrier frequency, ground constants, and polarization, figure 8.1 and annex III.4.

\(K_1\) A frequency and temperature-dependent attenuation coefficient for absorption within a cloud, (3.13) and table 3.1.

\(K_1, K_2, K, K, K_t\) Values of the diffraction parameter \(K\) for corresponding earth's radius \(a_1, a_2, a, a_s, a_t\), (8.8) to (8.13).

\(K(a), K(8497)\) The diffraction parameter \(K\) for an effective earth's radius \(a\), and for \(a = 8497\) km.

\(K(f, \text{GHz})\) A frequency-dependent coefficient used in computing the rate of absorption by rain, (3.9a) and figure 3.8.

\(L_{er}=L_{er}^*\) The effective loss factor for a receiving antenna, or the reciprocal of the power receiving efficiency, (2.3), \(L_{er} = 10 \log f_{er} \text{ db.}\)

\(L_{et}=L_{et}^*\) The effective loss factor for a transmitting antenna, (2.3), \(L_{et} = 10 \log f_{et} \text{ db.}\)

\(L\) Transmission loss expressed in decibels, (2.2).

\(L_b\) Basic transmission loss, (2.13) and (2.14).

\(L_{bd}\) Basic transmission loss for a diffraction path, (7.3), (7.4).

\(L_{bf}\) Basic transmission loss in free space, (2.16).
L_{bm} \quad \text{Hourly median basic transmission loss.}

L_{bsr} \quad \text{Reference value of long-term median basic transmission loss based on forward scatter loss, (9.1).}

L_c \quad \text{Calculated value of transmission loss.}

L_{cp} \quad \text{Polarization coupling loss, (2.10).}

L_{cr} \quad \text{Reference value of hourly median transmission loss when diffraction and scatter losses are combined, (9.14).}

L_{dr} \quad \text{Reference value of hourly median transmission loss due to diffraction, (9.14).}

L_f \quad \text{An "equivalent free-space transmission loss," (2.19).}

L_{gp} \quad \text{Loss in path antenna gain, defined as the difference between the sum of the maximum gains of the transmitting and receiving antennas and the path antenna gain, (2.21).}

L_{Lr}, L_{Lr} \quad \text{Transmission line and matching network losses at the receiver and transmitter.}

L_o \quad \text{Path loss, defined as transmission loss plus the sum of the maximum free space gains of the antennas, (2.12).}

L_s \quad \text{The system loss expressed in decibels, defined by (2.1). System loss includes ground and dielectric losses and antenna circuit losses.}

L_{sr} \quad \text{Reference value of median forward scatter transmission loss, used with L_{dr} to obtain the reference value L_{cr}, (9.14).}

L(q), L(0.5) \quad \text{Long-term value of transmission loss not exceeded for a fraction q of hourly medians; L(0.5) is the median value of L(q), section 10.}

L_{b}(q), L_{b}(0.5) \quad \text{Long-term value of basic transmission loss not exceeded for a fraction q of hourly medians; L_{b}(0.5) is the median of L_{b}(q).}

M \quad \text{Liquid water content of a cloud measured in grams per cubic meter, (3.13).}

MHz \quad \text{Radio frequency in megahertz.}

n \quad \text{Refractive index of the atmosphere, section 4.}

n \quad \text{The ratio } \alpha / \delta_r \text{ used to compute } \hat{n}, (9.12).

\hat{n} \quad \text{Atmospheric refractive index at the surface of the earth, (4.1).}

\hat{n} \quad \text{A parameter used in calculating path antenna gain, (9.12).}

N \quad \text{Atmospheric refractivity defined as } N = (n-1) \times 10^6, \text{ section 4.}

N_0 \quad \text{Surface refractivity reduced to sea level, (4.3).}

N_0 \quad \text{The value of } N \text{ at the surface of the earth, (4.1).}

\hat{p}(\hat{r}), \hat{p}_1(\hat{r}) \quad \text{Complex polarization vectors, section 2.3 and annex II.}

\frac{|\hat{p} \cdot \hat{p}_r|}{2} \quad \text{Polarization efficiency for transfer of energy in free space at a single radio frequency, (2.11) and (II.62).}

q \quad \text{Time availability, the fraction of time a given value of transmission loss is not exceeded, section 10.}

q \quad \text{The ratio } q = r_2 / r_1 \text{ used to compute } \Delta \psi_o, (9.5).

r \quad \text{The length in free space of the direct ray path between antennas, figure 5.1.}

r \quad \text{Radius of curvature, (7.9).}
Effective distance for absorption by oxygen in the atmosphere, (3.4) figures 3.2 to 3.4.

Effective rain-bearing distance, (3.11) and (3.12) figures 3.10 to 3.13.

Effective distance for absorption by water vapor in the atmosphere, (3.4), figures 3.2 to 3.4.

Length of a direct ray between antennas over an effective earth of radius a, figure 5.1.

Parameters used in computing the frequency gain function \( H_o \), and defined by (9.4).

Distances whose sum is the path length of a reflected ray, figure 5.1.

Direction of the most important propagation path from the transmitter to the receiver, or from the receiver to the transmitter.

Straight line distances from transmitting and receiving antennas to a point on the ground a distance \( x_i \) from the transmitting antenna, figure 6.4.

Abbreviation of root-mean-square.

The magnitude of the theoretical coefficient \( R \exp[-i(\pi-c)] \) for reflection of a plane wave from a smooth plane surface of a given conductivity and dielectric constant, (5.1).

An "effective" ground reflection coefficient, (5.1).

Rainfall rate in millimeters per hour, (3.10).

Surface rainfall rate, (3.10).

Cumulative distribution of instantaneous path average rainfall rates, figure 3.14.

A function of \( L_{dr} - L_{cr} \), (9.14) figure 9.9.

Path asymmetry factor, \( s = \alpha_o / \beta_o \), (6.19).

Reference absolute temperature, \( T_o = 288.37 \) degrees Kelvin.

Temperature in the troposphere in degrees Kelvin.

Effective sky noise temperature in degrees Kelvin.

Abbreviation of Television Allocations Study Organization.

A parameter used in computing diffraction over a rounded obstacle, (III.26) and figure 7.5.

A parameter used in computing diffraction over an isolated obstacle, (7.1).

A parameter used with the calculated long-term reference value, \( L_{cr} \), to predict median long-term transmission loss, figure 10.1 equations (10.4) and (III.67).

The parameter \( V(0.5, d_e) \) for a given climatic region characterized by the subscript \( n \), (10.4) figure 10.1.

Radio frequency signal power that would be available from an equivalent loss-free receiving antenna, \( W_a = 10 \log w_a \) dbw, (2.2).

Radio frequency signal power available at the terminals of the receiving antenna, \( W'_a = 10 \log w'_a \) dbw, (2.1).

Total power radiated from the transmitting antenna in a given band of radio frequencies, \( W_t = 10 \log w_t \) dbw, (2.2).

Available power at the terminals of a hypothetical loss-free isotropic receiving antenna, assuming no orientation, polarization, or multipath coupling loss between transmitting and receiving antennas, (2.13).
A specified value, the discussion preceding (2.14).

A variable designating distance from an antenna, figure 6.4.

The $i^{th}$ distance from the transmitter along a great circle path, figure 6.4.

Parameters used to compute diffraction loss, (8.2) figures 8.5 and 8.6.

Parameters chosen to exclude terrain adjacent to either antenna which is not visible to the other in computing a curve fit, (5.15).

The average of distances $x_0$ and $x_20$, (5.15b).

Initial bearings from antenna terminals A and B, measured from true north, figure 6.3.

Terrain elevations, modified to account for the curvature of the earth, (6.10).

Modified terrain elevation, $y(x) = h(x) - x^2/(2a)$, (5.16).

Bearing from any point $B'$ along the great circle path $AB$, figure 6.3.

Long-term variability of $L_m$ or of $W_m$ in terms of hourly medians, (10.6) and (V.4).

Basic estimate of variability in a continental temperate climate, figure 10.2.

Basic estimate of variability as a function of effective distance, (10.6) figure 10.2.

Great circle path length between antenna terminals A and B, figure 6.3.

Great circle path distance between an antenna and an arbitrary point $B'$, figure 6.3.
The parameter $\alpha$ is defined in equation (3.9b) and plotted as a function of frequency on figure 3.9.

The angles $\alpha_{oo'p}$ modified by the corrections $\Delta\alpha_{oo'}, \Delta\beta_{oo'}$, (6.19).

The angles between a transmitter or receiver horizon ray and a line drawn between the antenna locations on an earth of effective radius, $a$, (6.18) figure 6.1.

The function $\alpha$ in (3.9b) as a function of frequency in GHz, figure 3.9.

Differential absorption in decibels per kilometer for oxygen under standard conditions of temperature and pressure, (3.4).

Rate of absorption by rain, (3.8).

Surface value of the rate of absorption by rain, (3.11).

Differential absorption in decibels per kilometer for water vapor under standard conditions of temperature and pressure and for a surface value of absolute humidity of 10 g/cc, (3.4).

Differential atmospheric absorption in $\text{dB/km}$ for a path length $r$, (3.1).

Differential rain absorption along a path $r$, (3.7).

Differential absorption in $\text{dB/km}$ for oxygen and water vapor, respectively, as a function of height, $h$, (3.3).

Absorption coefficient as a function of path distance $r$, (3.2) and (3.6).

The effective half-power semi-beamwidth for the receiving and transmitting antennas, respectively, (9.11) and (9.12).

Azimuthal and vertical semi-beamwidths, (2.6).

Correction terms applied to compute $\alpha_{oo'}, \beta_{oo'}$, (6.19) figure 6.9.

Depression of field strength below smooth earth values, (5.19).

A correction term used to compute the effective height for high antennas, (6.12) figure 6.7.

The path length difference between a direct ray, $r_0$, and a reflected ray, $\Delta r = r_1 + r_2 - r_0$, (5.4), (5.9) and (7.1).

Auxiliary functions used to check the magnitude of error in the graphical determination of diffraction attenuation, (8.5) figures 8.5 and 8.6.

A correction term applied to the frequency gain function, $H_0$, (9.5) and figure 9.4.

The refractivity gradient from the surface value, $N_s$, to the value of $N$ at a height of one kilometer above the surface, (4.2).

The correction terms $\Delta\alpha_{oo'}, \Delta\beta_{oo'}$ for values of $N_s$ other than 301, (6.21) figure 6.10.

The correction terms $\Delta\alpha_{oo'}, \Delta\beta_{oo'}$ for $N_s = 301$, (6.21) read from figure 6.9.

The correction $\Delta h_e$ as a function of $N_s$ and of receiver and transmitter heights $h_r$ and $h_t$, (6.12) figure 6.7.

A function of $h_o$ and $N_s$ used in computing $F_o$ and $H_0$, (9.3) and figure 9.2.

The angular distance, $\theta$, is the angle between radio horizon rays in the great circle plane defined by the antenna locations, (6.19).
Horizon elevation angles at the receiver and transmitter, respectively, (6.15).

\( \theta_{r}, \theta_{t} \)

Angle of elevation of a direct ray relative to the horizontal at the lower antenna, (5.12).

\( \theta_{h} \)

Angle of elevation above the horizontal, figures 3.2 to 3.4.

\( \theta_{o}, \theta_{oo} \)

Angle between radio horizon rays, assuming straight rays above an earth of effective radius, \( a \), figure 6.1.

\( \theta_{or}, \theta_{ot} \)

The angular elevation of a horizon ray at the receiver or transmitter horizon, (6.16) figure 6.1.

\( \lambda \)

Free space radio wave length, used for example in (2.7).

\( \mu \)

The ratio \( \delta_{r}/\delta_{t} \) used in (9.12) and figure 9.8.

\( \nu \)

A parameter that is half the value of \( \eta_{s} \), used in computing loss in antenna gain, (9.11), (9.12) and figure 9.7.

\( \nu \)

Radio frequency in hertz.

\( \pi \)

A constant, \( \pi \approx 3.14159264 \).

\( \rho \)

Correlation coefficient between two random variables.

\( \rho \)

Index of curvature for the crest curvature of a rounded obstacle in the great circle path direction, (7.8).

\( \rho_{ij} \)

The correlation between variations due to sources \( i \) and \( j \), (10.8).

\( \rho_{1a} \)

The correlation between variations \( Y \) and \( Y_{a} \), (10.9).

\( \rho_{1r} \)

The correlation between variations \( Y \) and \( Y_{r} \), (10.9).

\( \sigma_{h} \)

The root-mean-square deviation of great circle path terrain elevations relative to a smooth curve fitted to the terrain, (5.1).

\( \sigma_{c}(p) \)

The standard deviation corresponding to the variance \( \sigma_{c}^{2}(p) \).

\( \Sigma \)

A symbol to represent the summation of terms, as in (5.15) where \( \sum_{i=0}^{20} h_{i} \) means the sum of all values of \( h_{i} \) from \( i = 0 \) to \( i = 20 \).

\( \Phi(\nu, \rho) \)

The total phase lag of the diffracted field over an isolated rounded obstacle with reflections from terrain, (7.13).

\( \Phi(\nu, 0) \)

The total phase lag of the diffracted field over an ideal knife edge with ground reflections, (7.13).

\( \Phi_{A}, \Phi_{B} \)

Latitudes of antenna terminals \( A \) and \( B \), (6.1) to (6.9) figure 6.3.

\( \Phi_{B} \)

Latitude of an arbitrary point along the great circle path from \( A \) to \( B \), (6.7).

\( \psi \)

The grazing angle of a ray reflected from a point on the surface of a smooth earth, (5.1) figure 5.1, or grazing angle at a feuillet, annex IV.

\( \psi_{m} \)

Minimum grazing angle, section 5.1.

\( \psi_{p} \)

The acute angle between principal polarization vectors \( \bar{e}_{p} \) and \( \bar{e}_{pr} \), (2.11).

\( \Omega_{r}, \Omega_{t} \)

The half-power beamwidths of the receiving and transmitting antennas, respectively, (9.10).
